SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, JANUARY 8, 1881.

NOTICE TO SUBSCRIBERS.

We consider it due to those subscribers who have favored us with their subscriptions, previous to the publication of our club rates, that they should have the privileges of the list. They can therefore send us subscriptions for any or all of the publications named at the reduced double rates, less $4, the subscription price of "SCIENCE."

THE Report of the United States Fish Commission* for the year 1878 constitutes a volume of nearly 1,000 pages of interesting matter, and, from the economic interests involved, should command more than a passing attention from those who are desirous of having the natural resources of this country fully developed.

A large portion of the Report, relating to purely scientific work, will be highly appreciated by every naturalist. For instance, the first division of the work including researches into the character of the fishes belonging to the North American fauna, was in charge of Mr. G. Brown Goode, assisted by Dr. T. H. Bean; while it is sufficient to say that the collection and investigation of marine invertebrates was conducted by Professor A. E. Verrill, assisted by Mr. Richard Rathbun, Mr. Sanderson Smith and Mr. Warren Upham, to show the value of the researches in this direction.

Few persons will peruse this Report without feeling an obligation to Professor Spencer F. Baird for the very thorough manner in which he is carrying out the objects of this Commission; for the ground he proposes to cover would appall one of less experience.

The amount of labor involved in carrying out the work of this Commission may be estimated by a brief reference to the programme which Professor Baird has sketched for future guidance:

1st. The preparation of a series of reports upon the various groups of aquatic animals and plants of North America, especially those having relation to the wants or luxuries of mankind, to be afterwards published as monographs, with suitable illustrations.

2d. The distribution of specimens of aquatic animals and plants, not required for the National Museum, to the numerous educational and scientific establishments in the United States.

3d. A complete account of the physical character and conditions of the waters of the United States, as to chemical composition, temperature, etc., with special reference to their availability in nurturing the proper species of food fishes.

4th. A history and description of the various methods, employed in the United States, in the pursuit, capture and utilization of fishes and other aquatic animals.

5th. Statistics of the various branches of the American fisheries from the earliest dates to the present time, so as to show the development of this important industry and its actual condition.

6th. The establishment by the General Government, or in connection with the States, of a thoroughly reliable and exhaustive system of recording fishery statistics for the future.

7th. The bringing together in the National Museum not only of a complete collection of the aquatic animals and plants referred to, but illustrations of all apparatus or devices, used at home or abroad, in the prosecution of the fisheries.

8th. An investigation of the movements and habits of various kinds of fish, to serve as a basis for legislation, either by the General Government or by the States.

9. The arrangement of a code of regulations in respect to close seasons, and other matters of detail respecting the capture of fish.

10th. The stocking of the various waters of the United States with the fish most suited to them, either by artificial propagation or transfer, and the best apparatus and methods for accomplishing this object.

Professor Baird intends to supplement this immense amount of work by collecting and compiling statistics for the proper treatment of international questions connected with the common use, by the United States and the British Provinces, of the waters of the North Atlantic.

The volume before us bears ample proof of the power of Professor Baird and his assistants, to carry out this programme to its fullest extent, and if the work progresses at the present rate, its accomplishment will not be so far in the future as many would suppose.

*United States Commission of Fish and Fisheries, Part VI. Report of the Commissioner for 1878.
A. Inquiry into the Decrease of Food-Fishes.
B. The Propagation of Food-Fishes in the Waters of the United States. Washington Government Printing Office, 1880.

We do not propose in this notice to epitomize the report; we prefer to do more justice to the subject by presenting from time to time brief abstracts of the paper, some of which are very elaborate, occupying 160 pages of closely printed matter, and 90 illustrations.

That part of the report describing the success of the commission in propagating salmon has been anticipated by the public press, but many of the details now given are new and of great interest. Many persons in the East will be astonished at the large scale of the salmon fishery in the Western rivers, where seven to nine thousand fish are sometimes taken in one day. From one station (the St. Cloud river), fourteen millions of eggs of salmon were secured and embryonized—sufficient to keep up the supply being returned to the river, the remainder were sent East; 7,250,000 arrived in Chicago between the 3rd and 7th of October. The report states that, after supplying the home demand, 500,000 were presented to Canada, 100,000 to England, 100,000 to France, 100,000 to Holland, 250,000 to Germany and 200,000 to New Zealand.

In regard to shipments to the last named country, it is satisfactory to be able to state, that they not only arrived in perfect condition, but that by the latest advices the young fish were seen in every direction, promising to be the ancestors of a numerous progeny.

Reference is made to Professor W. O. Atwater's investigations upon the food qualities of various species of fishes, the chief facts relating to which we were able to present in an abstracted form, to the readers of "SCIENCE," a few weeks since.

Various attempts have been made to introduce live specimens of the English Sole, one of the most delicious and prolific of British fishes. The last attempt by Mr. Fred. Mather, whose skill in fish culture is acknowledged in the report, was unfortunately like the rest—a failure. Mr. Mather gives a very reasonable explanation of his want of success, and it must be admitted that he was not supplied with the necessary conveniences. During 1880, Captain Mortimer was more successful, and succeeded in placing living specimens of the Sole (*Solea vulgaris*) in New York harbor. Captain Mortimer explained to us that his apparatus consisted of a tank having a fixed cover, to which were attached two globes, the constant rolling of the vessel causing the water of the tank to pass to the globes and return, thus keeping up a constant aeration for the fish, which naturally remained at the bottom.

We reluctantly close our notice of this most valuable and interesting Report feeling that our task has been but half fulfilled. We shall, however, again take up the subject in greater detail, and present our readers with many facts of much scientific interest.

THE AMERICAN CHEMICAL SOCIETY.*

The January meeting of the above Society was held in their rooms, Monday evening, January 3, 1881, Prof. C. F. Chandler in the President's chair. The nominations of Messrs. James F. Slade, Theodore M. Hopke, A. F. Hoppick as regular, and of Mr. E. K. Dunham as associate members were made. The resignations of Prof. Ira Remsen, Prof. S. P. Sadtler and Mr. L. W. Drew, read and accepted. A motion for the reduction of the annual dues from $10 to $5 was favorably considered, and the day of meeting was changed from Thursday to Monday, so that in the future, meetings will be held on the first and third Mondays of each month, instead of on the corresponding Thursdays. There being no papers before the society, the meeting was adjourned. We add herewith a list of the officers chosen at the December meeting for the present year: President, Prof. C. F. Chandler; Vice-Presidents, A. R. Leeds, G. A. Koenig, E. R. Squibb, Charles A. Goessmann, Henry Morten, Ira Remsen; Corresponding Secretary, P. Casamajor; Recording Secretary, Albert H. Gallatin; Treasurer, W. H. Nichols; Librarian, E. Waller; Curators, W. Rupp, A. J. Rossi, A. A. Fesquet.

ON A THERMO-MAGNETIC THERMOSCOPE.

By SIR WILLIAM THOMSON.

This thermoscope is founded on the change produced in the magnetic moment of a steel magnet by change of temperature. Several different forms suggest themselves. The one which seems best adapted to give good results is to be made as follows:

1. Prepare an approximately astatic system of two thin hardened steel wires, $r\ b, r^1\ b^1$, each one centimetre long, one of them, $r\ b$, hung by a single silk fibre, and the other hung bifilarly from it by fibres about three centimetres long, so attached that the projections of the two on a horizontal plane shall be inclined at an angle of about .01 of a radian (or .57°) to one another.

2. Hang a very small, light mirror, bifilarly from the lower of the two wires.

3. Magnetize the two wires to very exactly equal magnetic moments in the dissimilar directions. This is easily done by a few successive trials, to make them rest as nearly as possible perpendicular to the magnetic meridian.

4. Take two pieces of equal and similar straight steel wire, well hardened, each two centimetres long, and about .04 centimetres diameter. Magnetize them equally and similarly, and mount them on a suitable frame to fulfil conditions.

5 and 6. Call them R B and $R^1\ B^1$, B and B^1 denoting the ends containing true north polarity (ordinarily marked B), and R R^1 true south (ordinarily marked red). The small letters, r, b, r^1, b^1, mark on the same plan the polarites of $r\ b$ and $r^1\ b^1$.

3. The magnets R B, $R^1\ B^1$, are to be relatively fixed in line on their frame with similar poles next one another, at a distance of about two centimetres asunder, as thus, R B . . . $B^1\ R^1$, with B B^1 = two centimetres.

6. This frame is to be mounted on a geometrical slide upon the case, within which the astatic pair, $r\ b$, $r^1\ b^1$, is hung in such a manner that the line of R B, B R bisects $r\ b$, approximately at right angles, and that R B B R may be moved by a micrometer screw through about a millimetre on each side of its central position, the line of motion being the line of R B, $B^1\ R^1$, and the "central position" being that in which B and B^1 are equi-distant from the centre of $r\ b$.

7. A lamp and scale, with proper focussing lens if the mirror is not concave, are applied to show and measure small deflections as in my mirror galvanometres and electrometer.

* Communicated by M. Benjamin, Ph. B.

8. Place the instrument with the needles approximately perpendicular to the magnetic meridian, turning it so as to bring b and b^1 to the south of the vertical plane bisecting the small angle between the projections of $r\ b$, $r^1\ b^1$ and r, and r^1 to the north side of it.

9. By aid of the micrometer screw bring the luminous image to its middle position on the scale.

10. Cause R B, B¹ R¹ to have different temperatures. The luminous image is seen to move in such a direction as is due to r approaching the cooler, and receding from the warmer of the two deflectors B R, B¹ R¹.—*Proceedings Royal Society, Edinburgh.*

THE UNITY OF NATURE.

BY THE DUKE OF ARGYLL.

IV.

ON THE LIMITS OF HUMAN KNOWLEDGE CONSIDERED WITH REFERENCE TO THE UNITY OF NATURE.

And yet, although it is to Nature in this highest and widest sense that we belong—although it is out of this fountain that we have come, and it is out of its fullness that we have received all that we have and are, men have doubted, and will doubt again, whether we can be sure of anything concerning it.

If this terrible misgiving had affected individual minds alone in moments of weariness and despair, there would have been little to say about it. Such moments may come to all of us, and the distrust which they leave behind them may be the sorest of human trials. It is no unusual result of abortive yet natural effort and of innate yet baffled curiosity. But this doubt, which is really nothing more than a morbid effect of weakness and fatigue, has been embraced as a doctrine and systematized into a philosophy. Nor can it be denied that there are some partial aspects of our knowledge in which its very elements seem to dissolve and disappear under the power of self-analysis, so that the sum of it is reduced to little more than a consciousness of ignorance. All that we know of Matter is so different from all that we are conscious of in Mind, that the relations between the two are really incomprehensible and inconceivable to us. Hence this relation constitutes a region of darkness in which it is easy to lose ourselves in an abyss of utter skepticism. What proof have we—it has been often asked—that the mental impressions we derive from objects are in any way like the truth? We know only the phenomena, not the reality of things. We are conversant with things as they appear, not with things as they are "in themselves." What proof have we that these phenomena give us any real knowledge of the truth? How, indeed, is it possible that knowledge so "relative" and so "conditioned"—relative to a mind so limited, and conditioned by senses which tell us of nothing but sensations—how can such knowledge be accepted as substantial? Is it not plain that our conceptions of Creation and of a Creator are all mere "anthropomorphism?" Is it not our own shadow that we are always chasing? Is it not a mere bigger image of ourselves to which we are always bowing down?

It is upon suggestions such as these that the Agnostic philosophy, or the philosophy of Nescience, is founded—the doctrine that, concerning all the highest problems which it both interests and concerns us most to know, we never can have any knowledge or any rational and assured belief.

It may be well to come to the consideration of this doctrine along those avenues of approach which start from the conception we have now gained of the unity of Nature.

Nothing, certainly, in the human mind is more wonderful than this—that it is conscious of its own limitations. Such consciousness would be impossible if these limitations were in their nature absolute. The bars which we feel so much, and against which we so often beat in vain, are bars which could not be felt at all unless there were something in us which seeks a wider scope. It is as if these bars were a limit of opportunity rather than a boundary of power. No absolute limitation of mental faculty ever is, or ever could be, felt by the creatures whom it affects. Of this we have abundant evidence in the lower animals, and in those lower faculties of our own nature which are of like kind to theirs. All their powers and many of our own are exerted without any sense of limitation, and this because of the very fact that the limitation of them is absolute and complete. In their own nature they admit of no larger use. The field of effort and of attainable enjoyment is, as regards them, co-extensive with the whole field in view. Nothing is seen or felt by them which may not be possessed. In such possession all exertion ends and all desire is satisfied. This is the law of every faculty subject to a limit which is absolute. In physics, the existence of any pressure is the index of a potential energy which, though it may be doing no work, is yet always capable of doing it. And so in the intellectual world, the sense of pressure and confinement is the index of powers which under other conditions are capable of doing what they cannot do at present. It is in these conditions that the barrier consists, and at least to a large extent they are external. What we feel, in short, is less an incapacity than a restraint.

So much undoubtedly is to be said as to the nature of those limitations on our mental powers of which we are conscious. And the considerations thus presented to us are of immense importance in qualifying the conclusions to be drawn from the facts of consciousness. They do not justify, although they may account for, any feeling of despair as to the ultimate accessibility of that knowledge which we so much desire. On the contrary, they suggest the idea that there is within us a Reserve of Power to some unknown and indefinite extent. It is as if we could understand indefinitely more than we can discover, if only some higher Intelligence would explain it to us.

But if it is of importance to take note of this Reserve of Power of which we are conscious in ourselves, it is at least of equal importance to estimate aright the conceptions to which we can and do attain without drawing upon this reserve at all. Not only are the bars confining us bars which we can conceive removed, but they are bars which in certain directions offer no impediment at all to a boundless range of vision. Perhaps there is no subject on which the fallacies of philosophic phraseology have led to greater errors. "That the Finite cannot comprehend the Infinite," is a proposition constantly propounded as an undoubted and all-comprehensive truth. Such truth as does belong to it seems to come from the domain of Physics, in which it represents the axiom that a part cannot be equal to the whole. From this, in the domain of Mind, it comes to represent the truth, equally undeniable, that we cannot know all that Infinity contains. But the meaning into which it is liable to pass when applied to Mind is that Man cannot conceive Infinity. And never was any proposition so commonly accepted which, in this sense, is so absolutely devoid of all foundation. Not only is Infinity conceivable by us, but it is inseparable from conceptions which are of all others the most familiar. Both the great conceptions of Space and Time are, in their very nature, infinite. We cannot conceive of either of these as subject to limitation. We cannot conceive of a moment after which there shall be no more Time, nor of a boundary beyond which there is no more Space. This means that we cannot but think of Space as infinite, and of Time as everlasting.

If these two conceptions stood alone they would be enough, for in regard to them the only incapacity under which we labor is the incapacity to conceive the Finite. For all the divisions of Space and Time with which we are so familar,—our days and months and years, and our various units of distance,—we can only think of as bits and fragments of a whole which is illimitable. But although these great conceptions of Space and Time are possibly the only conceptions to which the idea of infinity attaches as an absolute necessity of Thought, they are by no means the only conceptions to which the same idea can be attached, and probably ought to be so. The conception of Matter is one, and the conception of Force is another, to which we do not perhaps attach, as of necessity, the idea of indestructibility, or the idea of eternal existence and of infinite extension. But it is remarkable that in exact proportion as science advances, we are coming to understand that both of

these are conceptions to which the idea of infinity not only may be, but ought to be attached. That is to say, that the eternal existence of Matter and the eternal duration of Force are not only conceivable but true. Nay, it may be our ignorance alone, that makes us think we can conceive the contrary. It is possible to conceive of Space being utterly devoid of Matter, only perhaps because we are accustomed to see and to think of spaces which are indeed empty of visible substances. We can expel also the invisible substances or gases of the atmosphere, and we can speak and think of the result as a vacuum. But we know now that when air and all other terrestrial gases are gone the luminiferous medium remains; and so far as we have means of knowing, this medium is ubiquitous and omnipresent in the whole universe of Space. In like manner we are accustomed to see solid matter so dissipated as to be invisible, intangible, and wholly imperceptible; and therefore we think we can imagine matter to be really destructible. But the more we know of it the more certain we become that it cannot be destroyed, and can only be redistributed. In like manner, in regard to Force, we are accustomed to see Matter in what is called statical equilibrium—that is to say, at rest; and so perhaps, we think, we can conceive the cessation or extinction of Force. But here again the progress of research is tending more and more to attach irrevocably the idea of indestructibility—that is, of eternal existence—to that which we know as Force. The truth is, that this conception is really implicitly involved in the conception of the indestructibility of Matter. For all that we know of Matter is inseparably connected with the forces which it exerts, or which it is capable of exerting, or which are being exerted in it. The force of gravitation seems to be all-pervading, to be either an inherent power or property in every kind, or almost every kind of Matter, or else to be the result of some kind of energy which is universal and unquenchable. All bodies, however passive and inert they may seem to be under certain conditions, yet indicate by their very existence the power of those molecular forces to which the cohesion of their atoms is due. The fact is now familiar to us that the most perfect stillness and apparent rest in many forms of Matter is but the result of a balance or equilibrium maintained between forces of the most tremendous energy, which are ready to burst forth at a moment's notice, when the conditions are changed under which that balance is maintained. And this principle, which has become familiar in the case of what are called explosive substances, because of the ease and the certainty with which the balanced forces can be liberated, is a principal which really prevails in the composition of all material substances whatever; the only difference being that the energies by which their molecules are held together are so held under conditions which are more stable—conditions which it is much more more difficult to change—and conditions, therefore, which conceal from us the universal prevalence and power of Force in the constitution of the material universe. It is, therefore, distinctly the tendency of science more and more to impress us with the idea of the unlimited duration and indestructible nature both of Matter and of the energies which work in and upon it.

One of the scientific forms under which this idea is expressed is the Conservation of Energy. It affirms that though we often see moving bodies stopped in their course, and the energy with which they move apparently extinguished, no such extinction is really effected. It affirms that this energy is merely transformed into other kinds of motion, which may or may not be visible, but which, whether visible or not, do always really survive the motion which has been arrested. It affirms, in short, that Energy, like Matter, cannot be destroyed or lessened in quantity, but can only be redistributed.

As, however, the whole existing Order of Nature depends on very special distributions and concentrations of Force, this doctrine affords no ground for presuming on the permanence, or even on the prolonged continuance, of that order. Quite the contrary; for another general conception has been attained from science which at first sight appears to be a contradiction of the doctrine of "Conservation of Energy"—namely, the "Dissipation of Energy." This doctrine, however, does not affirm that Energy can be dissipated in the sense of being wholly lost or finally extinguished. It only affirms that all the existing concentrations of force are being gradually exhausted, and that the forces concerned in them are being diffused (generally in the form of Heat) more and more equally over the infinitudes of Matter and of Space.

Closely connected with, if indeed it be not a necessary part and consequence of, these conceptions of the infinity of Space and time, of Matter and of Force, is the more general concept of Causation.

It is impossibe to conceive of anything happening without a cause. Even if we could conceive the utter destruction or annihilation of any particular force or form of force, we cannot conceive of this very destruction happening except as the effect of some cause. All attempts to reduce this idea of causation to other and lower terms have been worse than futile. They have uniformly left out something which is of the very essence of the idea. The notion of "uniform antecedence" is not equivalent. "Necessary antecedence" is more near the mark. These words do indeed indicate the essential element in the idea with tolerable clearness. But like all other simple fundamental conceptions, the idea of Causation defies analysis. As, however, we cannot dissociate the idea of Causation from the idea of Force or energy, it may perhaps be said that the indestructibility or eternal duration of Force is a physical doctrine which gives strength and substance to the metaphysical concept of causation. Science may discover, and indeed has already discovered, that, as regards our application of the idea of cause, and of the correlative idea of effect, to particular cases of sequence, there is often some apparent confusion arising from the fact that the relative positions of cause and effect may be interchangeable, so that A, which at one moment appears as the cause of B, becomes at another moment the consequence of B, and not its cause. Thus Heat is very often the cause of visible motion, and visible motion is again the cause of Heat. And so of the whole cycle of physical forces, which Sir W. Grove and others have proved to be "correlated"—that is, to be so intimately related that each may in turn produce or pass into all the others. But this does not really obscure or cast any doubt upon the truth of our idea of causation. On the contrary, that idea is confirmed in receiving a new interpretation, and in the disclosure of physical facts involving the same conception. The necessity of the connection between an effect and its cause receives an unexpected confirmation when it comes to be regarded as simply the necessary passing of an energy which is universal and indestructible from one form of action into another. Heat becomes the cause of Light because it is the same energy working in a special medium. Conversely Light becomes the cause of Heat, because again the same energy passes into another medium and there produces a different effect. And so all the so-called "correlated forces" may be interchangeably the cause or the consequence of each other, according to the order of time in which the changes of form are seen. This, however, does not confound, but only illustrates the ineradicable conviction that for all such changes there must be a cause. It may be perfectly true that all these correlated forces can be ideally reduced to different "forms of motion;" but motion itself is inconceivable except as existing in Matter, and as the result of some moving force. Every difference of direction in motion or of form in Matter implies a change, and we can conceive no change without a cause—that is to say, apart from the operation of some condition without which that change would not have been.

The same ultimate conceptions, and no other, appear to constitute all the truth that is to be found in a favorite doctrine among the cultivators of physical science— the so-called "Law of Continuity." This phrase is indeed often used with such looseness of meaning that it is extremely difficult to understand the primary signification attached to it. One common definition, or rather one common illustration, of this law is said to be that Nature does nothing suddenly—nothing "per saltum." Of course this can only be accepted under some metaphorical or transcendental meaning. In Nature there is such a thing as a flash of lightning, and this is generally recognized as sufficiently sudden. A great many other exertions of electric force are of similar rapidity. The action of chemical affinity is always rapid. and very often even instantaneous. Yet these are among the most common and the most powerful factors in the me-

chanism of Nature. They have the most intimate connection with the phenomena of Life, and in these the profoundest changes are often determined in moments of time. For many purposes to which this so-called "Law of Continuity" is often applied in argument no idler dogma was ever invented in the schools. There is a common superstition that this so-called law negatives the possibility, for example, of the sudden appearance of new forms of Life. What it does negative, however, is not appearances which are sudden, but only appearances which have been unprepared. Innumerable things may come to be,—in a moment—in the twinkling of an eye. But nothing can come to be without a long, even if it be a secret, history. The "Law of Continuity" is, therefore, a phrase of ambiguous meaning; but at the bottom of it there lies the true and invincible conviction that for every change, however sudden—for every "leap," however wide—there has always been a long chain of predetermining causes, and that even the most tremendous bursts of energy and the most sudden exhibitions of force have all been slowly and silently prepared. In this sense the Law of Continuity is nothing but the idea of Causation. It is founded on the necesary duration which we cannot but attribute to the existence of Force, and this appears to be the only truth which the Law of Continuity represents.

When now we consider the place in the whole system of our knowledge which is occupied by these great fundamental conceptions of Time and Space, and of Matter and of Force, and when we consider that we cannot even think of any one of these realities as capable of coming to an end, we may well be assured that, whatever may be the limits of the human mind, they certainly do not prevent us from apprehending infinity. On the contrary, it would rather appear that this apprehension is the invariable and necessary result of every investigation of nature.

It is indeed of the highest importance to observe that some of these conceptions, especially the indestructibility of Matter and of Force, belong to the domain of science. That is to say, the systematic examination of natural phenomena has given them distinctness and a consistency which they never possessed before. As now accepted and defined, they are the result of direct experiment. And yet, strictly speaking, all that experiment can do is to prove that in all cases in which either Matter or Force seems to be destroyed, no such destruction has taken place. Here then we have a very limited and imperfect amount of "experience" giving rise to an infinite conception. But it is another of the suggestions of the Agnostic philosophy that this can never be a legitimate result. Nevertheless, as a matter of fact, these conceptions have been reached. They are now universally accepted and taught as truths lying at the foundation of every branch of natural science—at once the beginning and the end of every physical investigation. They are not what are ordinarily called "laws." They stand on much higher ground. They stand behind and before every law, whether that word be taken to mean simply an observed order of facts, or some particular force to which that order is due, or some combinations of force for the discharge of function, or some abstract definition of observed phenomena such as the "laws of motion." All these, though they may be "invariable" so far as we can see, carry with them no character of universal or necessary truth—no conviction that they are and must be true in all places and for all time. There is no existing order—no present combinations of Matter or of Force—which we cannot conceive coming to an end. But when that end is come we cannot conceive but that something must remain,—if it be nothing else than that by which the ending was brought about or, as it were, the raw materials of the creation which, has passed away. That this conception, when once suggested and clearly apprehended, cannot be eradicated, is one of the most indisputable facts of instructed consciousness. That no possible amount of mere external observation or experiment can cover the infinitude of the conclusion is also unquestionably true. But if "experience" is to be upheld as in any sense the ground and basis of all our knowledge, it must be understood as embracing the most important of all kinds of experience in the study of Nature—the experience we have of the laws of Mind. It is one of the most certain of those laws, that in proportion as the powers of the understanding are well developed, and are prepared by previous training for the interpretation of natural facts, there is no relation whatever between the time occupied in the observation of phenomena and the breadth or sweep of the conclusions which may be arrived at from them. A single glance, lasting not above a moment of time, may awaken the recognition of truths as wide as the universe and as everlasting as Time itself. Nay, it has often happened in the history of science that such recognitions of general truths have been reached by no other kind of observation than that of the mind becoming conscious of its own innate perceptions. Conceptions of this nature have perpetually gone before experiment—have suggested it, guided it—and have received nothing more than corroboration from it. I do not say that these conceptions have been reached without any process. But the process has been to a large extent as unconscious as that by which we see the light. I do not say they have been reached without "experience," even in that narrow sense in which it means the observation of external things. But the experience has been nothing more than the act of living in the world, and of breathing in it, and of looking round upon it. These conceptions have come to Man because he is a Being in harmony with surrounding Nature. The human mind has opened to them as a bud opens to the sun and air. So true is this, that when reasons have been given for the conclusions thus arrived at—these reasons have often been quite erroneous. Nothing in the history of philosophy is more curious than the close correspondence between many ideas enunciated by the ancients as the result of the speculation, and some, at least, of the ideas now prevalent as the result of science. It is true that the ancients expressed them vaguely, associated them with other conceptions which are wide of the truth, and quoted in support of them illustrations which are often childish. Nevertheless the fact remains that they had attained to some central truths, however obscured the perception may have been by ignorance of the more precise and accurate analogies by which they can be best explained, and which only the process of observation has revealed. "They had in some way grasped," says Mr. Balfour Stewart,* "the idea of the essential unrest and energy of things. They had also the idea of small particles or atoms; and finally of a medium of some sort, so that they were not wholly ignorant of the most profound and deeply seated of the principles of the material universe." There is but one explanation of this, but it is all-sufficient. It is that the mind of Man is a part, and one at least of the highest parts, of the system of the universe—the result of mechanism most suited to the purpose of catching and translating into thought the light of truth as embodied in surrounding Nature.

We have seen that the foundations of all conscious reasoning are to be found in certain propositions which we call self-evident. That is to say, in propositions the truth of which is intuitively perceived. We have seen, too, as a general law affecting all manifestations of Life or Mind, even in its very lowest forms, that instinctive or intuitional perceptions are the guide and index of other and larger truths which lie entirely beyond the range of the perception or intuition which is immediately concerned. This law holds good quite as much of the higher intuitions which are peculiar to Man as of the mere intuitions of sensation which are common to him and to the animals beneath him. The lowest savage does many things by mere instinct which contain implicitly truths of a very abstract nature—truths of which, as such, he has not the remotest conception, and which in the present undeveloped condition of his faculties it would be impossible to explain to him. Thus, when he goes into the forest to cut a branch fit for being made into a bow, or when he goes to the marsh to cut a reed fit for being made into an arrow, and when in doing so he cuts them off the proper length by measuring them by the bows and arrows which he already has, in this simple operation he is acting on the abstract and most fruitful truth that "things equal to the same thing are equal to one another." This is one of the axioms which lie at the basis of all mathematical demonstration. But as a general, universal, and necessary truth the savage knows nothing of it—as little as he knows of the wonderful consequences to which it will some day lead his children or descendants. So in like

* "Conservation of Energy," p. 135.

manner when the savage designs, as he often does, most ingenious traps for the capture of his prey, and so baits them as to attract the animals he desires to catch, he is counting first on the constancy and uniformity of physical causation, and, secondly, on the profoundly different action of the motives which determine the conduct of creatures having Life and Will. But of neither of these as general truths does he know anything, and of one of them at least, not even the greatest philosophers have reached the full depth of meaning. Nevertheless, it would be a great error to suppose that the savage, because he has no conception of the general truth involved in his conduct, has been guided in that conduct by anything in the nature of chance or accident. His intuitions have been right, and have involved so much perception of truth as is necessary to carry him along the little way he requires to travel, because the mind in which those intuitions lie is a product and a part of Nature—a product and part of that great system of things which is held together by laws intelligible to Mind—laws which the human mind has been constructed to feel even when it cannot clearly see. Moreover, when these laws come to be clearly seen, they are seen only because the mind has organs adjusted to the perception of them, and because it finds in its own mechanism corresponding sequences of thought.

It was the work of a great German metaphysician towards the close of the last century to discriminate and define more systematically than had been done before some at least of those higher elements of thought which, over and above the mere perception of external things, the mind thus contributes out of its own structure to the fabric of knowledge. In doing this he did immortal service—proving that when men talked of "experience" being the source of knowledge, they forgot that the whole process of experience presupposes the action of innate laws of thought, without which experience can neither gather its facts nor reach their interpretation. "Experience," as Kant most truly said, is nothing but a "synthesis of intuitions"—a building up or putting together of conceptions which the access of external Nature finds ready to be awakened in the mind. The whole of this process is determined by the mind's own laws—a process in which even observation of outward fact must take its place according to principles of arrangement in which alone all explanations of them consists, and out of which any understanding them is impossible.

And yet this great fact of a large part of our knowledge—and that the most important part—coming to us out of the very furniture and constitution of the mind itself, has been so expressed and presented in the language of philosophy as rather to undermine than to establish our confidence in the certainty of knowledge. For if the mind is so spoken of and represented as to suggest the idea of something apart from the general system of Nature, and if its laws of thought are looked upon as "forms" or molds into which, by some artificial arrangement or by some mechanical necessity, everything from outside must be squeezed and made to fit—then it will naturally occur to us to doubt whether conceptions cut out and manufactured under such conditions can be any trustworthy representation of the truth. Such, unfortunately, has been the mode of representation adopted by many philosophers—and such accordingly has been the result of their teaching. This is the great source of error in every form of the Idealistic philosophy, but it is a source of error which can be perfectly eliminated, leaving untouched and undoubted the large body of truths which has made that philosophy attractive to so many powerful minds. We have only to take care that in expressing those truths we do not use metaphors which are misleading. We have only to remember that we must regard the mind and the laws of its operation in the light of that most assured truth—the Unity of Nature. The mind has no "molds" which have not themselves been molded on the realities of the universe—no "forms" which it did not receive as a part and a consequence of a unity with the rest of Nature. Its conceptions are not manufactured; they are developed. They are not made; they simply grow. The order of the laws of thought under which it renders intelligible to itself all the phenomena of the universe, is not an order which it invents, but an order which it simply feels and sees. And this "vision and faculty divine" is a necessary consequence of its congenital relations with the whole system of Nature—from being bone of its bone—flesh of its flesh—from breathing its atmosphere, from living in its light, and from having with it a thousand points of contact visible and invisible, more than we can number or understand.

And yet so subtle are the suggestions of the human spirit in disparagement of its own powers—so near and ever present to us is that region which belongs to the unsatisfied Reserve of Power—that the very fact of our knowledge arising out of our organic relations with the rest of Nature has been seized upon as only casting new discredit on all that we seem to know. Because all our knowledge arises out of these relations, therefore, it is said, all our knowledge of things must be itself relative; and relative knowledge is not knowledge of "things in themselves." Such is the argument of metaphysicians—an argument repeated with singular unanimity by philosophers of almost every school of thought. By some it has been made the basis of religious proof. By some it has been made the basis of a reasoned skepticism. By some it has been used simply to foil attacks upon belief. The real truth is that it is an argument useless for any purpose whatever, because it is not itself true. The distinction between knowledge of things in their relations, and knowledge of things "in themselves," is a distinction without a meaning. In metaphysics the assertion that we can never attain to any knowledge of things in themselves does not mean simply that we know things only in a few relations out of many. It does not mean even that there may be and probably are a great many relations which we have not faculties enabling us to conceive. All this is quite true, and a most important truth. But the metaphysical distinction is quite different. It affirms that if we knew things in every one of the relations that affect them, we should still be no nearer than before to a knowledge of "things themselves." "It is proper to observe," says Sir W. Hamilton, "that had we faculties equal in number to all the possible modes of existence, whether of mind or matter, still would our knowledge of mind or matter be only relative. If material existence could exhibit ten thousand phenomena,—if we possessed ten thousand senses to apprehend these ten thousand phenomena of material existence, of existence absolutely and in itself we should then be as ignorant as we are at present."* The conception here that there is something to be known about things in which they are not presented as in any relation to anything else. It affirms that there are certain ultimate entities in Nature to which all phenomena are due, and yet which can be thought of as having no relation to these phenomena, or to ourselves, or to any other existence whatever. Now as the very idea of knowledge consists in the perception of relations, this affirmation is, in the purest sense of the word, nonsense—that is to say, it is a series of words which have either no meaning at all or a meaning which is self-contradictory. It belongs to the class of propositions which throw just discredit on metaphysics—mere verbal propositions, pretending to deal with conceptions which are no conceptions at all, but empty sounds. The "unconditioned," we are told, "is unthinkable;" but words which are unthinkable had better be also unspeakable, or at least unspoken. It is altogether untrue that we are compelled to believe in the existence of anything which is "unconditioned"—in Matter with no qualities—in Minds with no character—in a God with no attributes. Even the metaphysicians who dwell on this distinction between the Relative and Unconditioned admit that it is one to which no idea can be attached. Yet, in spite of this admission, they proceed to found many inferences upon it, as if it had an intelligible meaning. Those who have not been accustomed to metaphysical literature could hardly believe the flagrant unreason which is common on this subject. It cannot be better illustrated than by quoting the words in which this favorite doctrine is expressed by Sir William Hamilton. Speaking of our knowledge of Matter he says: "It is a name for something known—for that which appears to us under the forms of extension, solidity, divisibility, figure, motion, roughness, smoothness, color, heat, cold," etc. "But," he goes on to say, "as these phenomena appear only in conjunction, we are compelled by the constitution of our nature to think them conjoined in and by something; and as they

* "Lectures," vol. i. p. 145.

are phenomena, we cannot think them the phenomena of nothing, but must regard them as the properties or qualities of something that is extended, figured, etc. But this something, absolutely and in itself—*i. e.*, considered apart from its phenomena—is to us as Zero. It is only in its qualities, only in its effects, in its relative or phenomenal existence, that it is cognizable or conceivable; and it is only by a law of thought which compels us to think something absolute and unknown, as the basis or condition of the relative and known, that this something obtains a kind of incomprehensible reality to us." The argument here is that because phenomena are and must be the "properties or qualities of something else," therefore we are "compelled to think" of that something as having an existence separable from any relation to its own qualities and properties, and that this something acquires from this reasoning a "kind of incomprehensible reality!" There is no such law of thought. There is no such necessity of thinking nonsense as is here alleged. All that we are compelled to think is that the ultimate constitution of Matter, and the ultimate source of its relations to our own organism, are unknown, and are probably inaccessible to us. But this is a very different conception from that which affirms that if we did know or could know these ultimate truths, we should find in them anything standing absolutely alone and unrelated to other existences in the Universe.

It is, however, so important that we should define to ourselves as clearly as we can the nature of the limitations which affect our knowledge, and the real inferences which are to be derived from the consciousness we have of them, that it may be well to examine these dicta of metaphysicians in the light of specific instances. It becomes all the more important to do so, when we observe that the language in which these dicta are expressed generally implies that knowledge which is "only relative" is less genuine or less absolutely true than some other kind of knowledge which is not explained, except that it must be knowledge of that which has no relation to the mind.

There is a sense (and it is the only sense in which the words have any meaning) in which we are all accustomed to say that we know a thing "in itself," when we have found out, for example, its origin, or its structure, or its chemical composition as distinguished from its more superficial aspects. If a new substance were offered to us as food, and if we examined its appearance to the eye, and felt its consistency to the touch, and smelt its odor, and finally tasted it, we should then know as much about it as these various senses could tell us. Other senses, or other forms of sensation, might soon add their own several contributions to our knowledge, and we might discover that this substance had deleterious effects upon the human organism. This would be knowing, perhaps, by far the most important things that are to be known about it. But we should certainly like to know more, and we should probably consider that we had found out what it was "in itself," when we had discovered farther, for example, that it was the fruit of a tree. Chemistry might next inform us of the analysis of the fruit, and might exhibit some alkaloid to which its peculiar properties and its peculiar effects upon the body are due. This, again, we should certainly consider as knowing what it is "in itself." But other questions respecting it would remain behind. How the tree can extract this alkaloid from the inorganic elements of the soil, and how, when so extracted, it should have such and such peculiar effects upon the animal body; these, and similar questions, we may ask, and probably we shall ask in vain. But there is nothing in the inaccessibility of this knowledge to suggest that we are absolutely incapable of understanding the answer if it were explained to us. On the contrary, the disposition we have to put such questions raises a strong presumption that the answer would be one capable of that assimilation by our intellectual nature in which all understanding of anything consists. There is nothing in the series of phenomena which this substance has exhibited to us—nothing in the question which they raise which can even suggest the idea that all these relations which we have traced, or any others which may remain behind, are the result of something which can be thought of or conceived as neither a cause nor a consequence—but solitary and unrelated. On the contrary, all that remains unexplained is the nature and cause of its relations—its relations on the one hand to the elements out of which vegetable vitality has combined it, and its relations on the other hand to the still higher vitality which it threatens to destroy. Its place in the unity of Nature is the ultimate object of our search, and this unity is essentially a unity of relations, and of nothing else. That unity everywhere proclaims the truth that there is nothing in the wide universe which is unrelated to the rest.

Let us take another example. Until modern science had established its methods of physical investigation, Light and Sound were known as sensations only. That is to say, they were known in terms of the mental impressions which they immediately produce upon us, and in no other terms whatever. There was no proof that in these sensations we had any knowledge "in themselves" of the external agencies which produce them. But now all this is changed. Science has discovered what these two agencies are "in themselves;"—that is to say, it has defined them under aspects which are totally distinct from seeing or hearing, and is able to describe them in terms addressed to wholly different faculties of conception. Both Light and Sound are in the nature of undulatory movements in elastic media—to which undulations our organs of sight and hearing are respectively adjusted or "attuned." In these organs, by virtue of that adjustment or attuning, these same undulations are "translated" into the sensations which we know. It thus appears that the facts as described to us in this language of sensation are the true equivalent of the facts as described in the very different language of intellectual analysis. The eye is now understood to be an apparatus for enabling the mind instantaneously to appreciate differences of motion which are of almost inconceivable minuteness. The pleasure we derive from the harmonies of color and of sound, although mere sensations, do correctly represent the movement of undulations in a definite order; whilst those other sensations which we know as discords represent the actual clashing and disorder of interfering waves. In breathing the healthy air of physical discoveries such as these, although the limitations of our knowledge continually haunt us, we gain nevertheless a triumphant sense of its certainty and of its truth. Not only are the mental impressions, which our organs have been so constructed as to convey, a true interpretation of external facts, that the conclusions we draw as to their origin and their source, and as to the guarantee we have for the accuracy of our conceptions, are placed on the firmest of all foundations. The mirror into which we look is a true mirror, reflecting accurately and with infinite fineness the realities of Nature. And this great lesson is being repeated in every new discovery, and in every new application of an old one. Every reduction of phenomena to ascertained measures of force; every application of mathematical proof to theoretical conceptions; every detection of identical operations in diverse departments of Nature; every subjection of material agencies to the service of mankind; every confirmation of knowledge acquired through one sense by the evidence of another—every one of these operations adds to the verifications of science, confirms our reasonable trust in the faculties we possess and assures us that the knowledge we acquire by the careful use of these is a real and substantial knowledge of the truth.

If now we examine the kind of knowledge respecting Light and Sound which recent discoveries have revealed to us, as compared with the knowledge which we had of them before these discoveries were made, we shall find out that there is an important difference. The knowledge which we had before was the simple and elementary knowledge of sensation. As compared with that knowledge, the new knowledge we have acquired respecting light and sound, is a knowledge of these things "in themselves." Such is the language in which we should naturally express our sense of that difference, and in so expressing it we should be expressing an important truth. The newer knowledge is a higher knowledge than the older and simpler knowledge which we had before. And why? Wherein does this higher quality of the new knowledge consist? Is it not in the very fact that the new knowledge is the perception of a higher kind of relation than that which we had perceived before? There is no difference between the two kinds of knowledge in respect to the mere abstract character of relativity. The old was as relative as the new; and the new is as relative as the old. Before the new discoveries sound

was known to come from sonorous bodies, and light was known to come from luminous bodies. This was a relation—but a relation of the vaguest and most general kind. As compared with this vague relation the new relation under which we know them is knowledge of a more definite and of a higher kind. Light and Sound we now know to be words or ideas representing not merely any one thing or any two things, but especially a relation of adjustment between a number of things. In this adjustment Light and Sound, as known to sense do "in themselves" consist. Sound becomes known to us as the attunement between certain aerial pulsations and the auditory apparatus. Light becomes known to us as a similar or analogous attunement between the ethereal pulsations and the optic apparatus. Sound in this sense is not the aerial waves "in themselves," but in their relation to the ear. Light is not the ethereal undulations "in themselves," but in their relation to the eye.

It is only when these come into contact with a pre-arranged machinery that they become what we know and speak of as Light and Sound. This conception, therefore, is found to represent and express a pure relation; and it is a conception higher than the one we had before, not because it is either less or more relative, but because its relativity is to a higher faculty of the intellect or the understanding.

And, indeed, when we come to think of it, we see that all kinds of knowledge must take their place and rank according to this order of precedence. For, as all knowledge consists in the establishment of relations between external facts and the various faculties of the mind, the highest knowledge must always be that in which such relations are established with those intellectual powers which are of the highest kind. Hence we have a strictly scientific basis of classification for arranging the three great subjects of all human inquiry—the What, the How, and the Whence or Why. These are steps in an ascending series. What things are, how they come to be, and for what purpose they are intended in the whole system of Nature—these are the questions, each rising above the other, which correspond to the order and the rank of our own faculties in the value and importance of their work.

It is the result of this analysis to establish that, even if it were true that there could be anything in the Universe existing out of relation with other things around it, or if it were conceivable that there could be any knowledge of things as they so exist, it would be no higher knowledge, but infinitely lower knowledge than that which we actually possess. It could at the best be only knowledge of the "What," and that, too, in the lowest conceivable form—knowledge of the barest, driest, nakedest existence, without value or significance of any kind. And further, it results from the same analysis that the relativity of human knowledge, instead of casting any doubt upon its authenticity, is the very characteristic which guarantees its reality and its truth. It results further, that the depth and completeness of that knowledge depends on the degree in which it brings the facts of Nature into relation with the highest faculties of Mind.

It must be so if Man is part of the great system of things in which he lives. It must be so, especially if in being part of it, he is also the highest visible part of it—the product of its "laws" (as regards his own little corner of the Universe) the consummation of its history.

Nor can there be any doubt as to what are the supreme faculties of the human mind. The power of initiating changes in the order of Nature, and of shaping them from the highest motives to the noblest ends—this, in general terms, may be said to include or to involve them all. They are based upon the ultimate and irresolvable power of Will, with such freedom as belongs to it; upon the faculty of understanding the use of means to ends, and upon the Moral Sense which recognizes the law of righteousness and the ultimate Authority on which it rests. If the Universe or any part of it is ever to be really understood by us—if anything in the nature of an explanation is ever to be reached concerning the system of things in which we live, these are the perceptive powers to which the information must be given—these are the faculties to which the explanation must be addressed. When we dedesire to know the nature of things "in themselves," we desire to know the highest of their relations which are conceivable to us: we desire, in the words of Bishop Butler, to know "the Author, the cause and the end of them."

ASTRONOMY.

ELEMENTS OF SWIFT'S COMET.

COMPUTED BY PROFESSOR E. FRISBY, U. S. NAVAL OBSERVATORY, WASHINGTON.

[Communicated by Rear Admiral John Rodgers, U. S. Navy, Superintendent.]

To the Editor of SCIENCE:

The following elements of Swift's comet have been computed by Professor Frisby from three observations made with the Transit Circle at Washington by Professor Eastman on the nights of October 25th, November 7th and 20th, with these results. No assumptions about any periodic time have been made.

Epoch—Perihelion passage.
November 7.77568d, Wash. M. T.

$$\left.\begin{array}{rl} \Omega = & 296^\circ\ 48'\ 19''.9 \\ \pi = & 42\ \ 59\ \ 15\ .8 \\ \phi = & 42\ \ 26\ \ 48\ .5 \\ i = & 5\ \ 30\ \ 35\ .9 \\ \log a = & 0\ .517002 \\ \log \mu = & 2''.774504 \end{array}\right\}\ \text{Mean equinox 1880.0}$$

The comet approached very near to the Earth on November 20th, its distance being less than $\frac{1}{7}$th of the Sun's distance. We have for the dates given:

	log r	log Δ
October 25	0.035328	9.221510
November 7	0.029018	9.141693
" 20	0.034558	9.119295

Its perihelion distance thus appears to be a little greater than the distance of the Earth; and its aphelion lies just beyond Jupiter's orbit. The periodic time from these observations being about 2178d., or a little less than 6 years, there can be no doubt that the preiodic time of about 5½ years is the correct one.

U. S. NAVAL OBSERVATORY, WASHINGTON, D. C.,
January 6, 1881.

THE SOLAR ECLIPSE.—The last contact of the partial solar eclipse on the morning of December 31, 1880, was seen at Harvard College Observatory under quite favorable circumstances. The mean of six observations by as many different observers gives:

Last contact, December 30, 21h. 13m. 3s. Cambridge Mean Time.

At the United States Naval Observatory the last contact was observed by Prof. Hall, with a comet seeker of 4in. aperture and magnifying power of 19 diameters, as follows:

Last contact, December 30, 20h. 32m. 36s. Washington Mean Time. Owing to the extremely low temperature (11 degrees below zero, Fahr.) at Washington, the images were very poor and the observation somewhat uncertain. W. C. W.

NEW YORK MICROSCOPICAL SOCIETY.

The annual meeting for the selection of officers for the year 1881, took place on the 31st ultimo, when the following officers were elected: President, Romyn Hitchcock; Vice-President, E. C. Bogart; Recording Secretary, W. H. Mead; Corresponding Secretary, Benjamin Braman; Treasurer, W. C. Hubbard; Curator, Dr. Deems.

This Society will shortly give a public *conversazione*, when a variety of interesting objects will be exhibited, and an opportunity afforded to Microscopists to examine many new forms of Microscope stands which have been recently produced. Those who desire to assist or be present on this occasion should address Professor Romyn Hitchcock, 53 Maiden Lane, N. Y.

EPHEMERIS OF SWIFT'S COMET.

The following is a continuation of Mr. Upton's Ephemeris, which he has corrected by observations made at Washington up to Jan. 7, 1881. Mr. Wendell, at Harvard College Observatory, obtained an observation for position on Jan. 3, and Prof. Hall is of the opinion that the comet can be followed without great difficulty, even after the present moon.

EPHEMERIS—WASHINGTON MIDNIGHT.

1881	R. A. h. m. s.	Dec. ° ′
Jan. 11	6 0 26	+26 57.4

WASHINGTON, D. C., January 8, 1881. W. C. W.

ECLIPSE OF THE SUN.

The partial eclipse of the Sun which occurred on December 31, 1880, was observed with the spectroscope at my private observatory.

For this purpose, the instrument was so adjusted that it would present its slit radially to the limb of the Moon; and the C line was placed in the centre of the field, in order to see any solar protuberance that might be at the place of observation.

At about the time of greatest obscuration, the slit was directed on the Moon's limb outside of the Sun, at some distance from its western cusp. Although the limb of the Moon was absolutely invisible in the telescope outside of the Sun, as ascertained before, yet, the presence of the satellite was immediately made known in the spectroscope, where it gave a very distinct broad grayish band spectrum, running along the brighter spectrum of the vicinity of the Sun.

The phenomenon became more apparent the nearer the slit was moved towards the Sun, and it vanished from sight when it was at a distance estimated at 3 or 4 minutes from the solar limb.

As the eclipse drew nearer the end, the phenomenon became less and less conspicuous on the western side, and at about 9 o'clock it had almost entirely ceased.

An unsuccessful attempt was made to observe the phenomenon taking place at the point of last contact, when the Moon's limb left that of the Sun. For this purpose the slit of the instrument was placed radially to the point of emergence. But either because no phenomenon was perceptible, or perhaps rather because the slit was not exactly at the right place, nothing was seen.

If the dull spectrum obtained when the slit of the spectroscope was placed in the immediate vicinity of the Sun was due only to the solar light, which is reflected by our atmosphere, it is plain that this spectrum would have been as bright on the Moon as it was outside of it, since the terrestrial atmosphere lies as necessarily between the observer and the Moon as it does between us and the Sun, and therefore no dark-band spectrum could have been seen. But as it was visible, it must be inferred that besides the spectrum given off by the solar light reflected by our atmosphere, there must have been some other light, either emitted or reflected, coming from a point situated beyond the Moon, which reinforced the spectrum given off by the solar light reflected by our atmosphere.

This light, undoubtedly, can be no other than that of the solar atmosphere, or Corona, visible during total eclipses of the Sun.

If this reasoning is sound, the conclusions to be drawn from these observations are that the Corona, or at least traces of it, was visible during this partial eclipse, and that it was much brighter in the northwest equatorial regions than it was in the East; and, furthermore, that in the West it was less and less brilliant as it was observed northward, until it was completely invisible in the northern regions of the Sun. L. TROUVELOT.

CAMBRIDGE, *December* 31, 1880.

JUPITER.

OBSERVATIONS OF THE GREAT RED SPOT.

Having devoted most of my observing time this year to the phenomenæ of Jupiter, I would respectfully submit a few observations of the great red spot, situated in the south temperate zone of the planet.

Up to December 14, (the last observation on account of cloudy weather,) I have observed forty transits of the red spot across the central meridian. Thirty-four of these have been complete transits, *i. e.*, the preceding end the middle and the following end being observed.

The following table contains twenty-nine of these transits and is given in Greenwich mean time. The first, third and fifth columns give the observed time of passage of the preceding end, the middle and the following end of the spot.

Columns two, four and six, contain the times by which each portion of the spot preceded the passage of an assumed meridian that has a rotation period of $9^h\ 55^m\ 27.^s08$ (an ephemeris of the transits of this meridian has been published at intervals in the *English Mechanic*, by Herr A. Marth of the Royal Astronomical Society, and is corrected for parallax, velocity of light and phase).

The last column (7) contains the duration of transit in minutes, that is, the interval between the passage of the *P* and *F ends.*

TRANSIT OF JUPITER'S GREAT RED SPOT.

The above table shows that the red spot varies considerably in length. These variations are shown in the last column, marked "Duration of Transit."

Assuming that the red spots period of rotation is 9^h 55^m $37^s.065$—which is probably very near the truth—we find that in one minute of time $0^\circ.604$ of the surface will pass a given meridian. Multiplying the minutes in the last, or column 7, by .604, we get the following table of lengths in longitude on the surface of Jupiter. The first nine are taken from a table of eleven transits observed by me previous to August 30, and published in *English Mechanic*, No. 809:

July 10, 1880	40°.45	Oct. 6, 1880	33°.82

" 30, "	31 .71	" 9, "	28 .87
Oct. 1, "	33 .04	" 14, "	29 .11

On July 10 the spot had a narrow strip running from its preceding end. To this is due the great length of the spot on that date. This does not indicate the true length of the spot proper, but as it was a portion of the spot, or continuation, I give the length on that date.

It must not be supposed that, because I have carried the lengths to two places in the decimals, I consider the length accurate to that degree, for the observations have been entirely eye estimations, yet they were very carefully made. I think a variation of one degree in the length of the spot would be easily detected, and probably a less amount, as the agreement between most of the figures is too close and regular to attribute to chance. As my method of observing may be of interest, I will give an example from my note book. First: I watch closely the first end of the spot, and imagine a line dropped from it to the equatorial belt and observe when this is central, for it is much easier to halve the straight edge-like line of the equatorial belt than to halve the disk on a parallel with the spots centre, because the spot itself being on one side of the meridian biases our judgment to a certain extent, while the clean edge of the equatorial belt is free of any obstacle to interfere with our judgment. Second: I compare the spaces between the limbs of the planet and the ends of the spot, when these are seen to be equal, of course the spots centre is in transit. For determining the transit of the following end, the same method as that in determining the preceding end is followed. At the observation of each part of the spot there exists for a short while a period of uncertainty. The beginning of this uncertainty I indicate by *u*, noting the time. In a minute or so I feel sure the time of true phase has arrived, this is noted by *t*, with its time. Shortly, I am certain the phase has passed, this I note as *c*, with its time. The mean of the three is taken for the true phase.

The following is an observation of the transit of the red spot on October 13, 1880, Nashville, *mt*, taken from my note book.

	h. m.		
	u 7 40	*h. m.*	
P	*t* 7 44	7 44	
	c 7 48		
	u 8 07	*h. m.*	*h m.*
M	*t* 8 10	8 10	**8 09.9**
	c 8 13		
	u 8 32.5	*h. m.*	
F	*t* 8 36 5	8 35.8	
	c 8 38.5		

The mean of the nine observations agrees with the observed middle transit to .1 m. This close agreement cannot, of course, be expected often. However, they generally agree to within a few fractions of a minute. In no case have I allowed myself to know beforehand what time any phase *should* occur, as this might influence the observations.

The variations in length of the spot are not only shown by the duration of transit, but are sensible to an observing eye. At each observation I estimate its length, comparing it with the breadth of the disk on the same parallel of latitude. These comparisons show changes in its length, as they vary from 1-3.5 to ⅓ the breadth of the disk, but it is generally the slightest bit less than one-third.

The variations in breadth are compared with the great equatorial band, but unfortunately this is a standard that probably varies itself. The spot's breadth is generally slightly less than ½ the width of the equatorial belt, sometimes it is probably fully half as broad as the belt, but I have never seen it broader than that.

Changes in the width of the space between the south edge of the equatorial belt and the north edge of the spot, are more readily detected, as the space can be easily compared with the breadth of the spot. This space is generally equal to ⅓ the spot's breadth, yet it is sometimes nearly one-half as broad as the spot. I have seen it diminished to one-sixth. These changes are due either to a swelling out of the spot or a broadening of the equatorial belt. It is more likely due to changes in the spot. I have on several occasions estimated that the distance between the southern edge of the equatorial band and the southern edge of the spot was about equal to one-third the distance from the south pole to the equatorial belt.

There are sometimes slight changes in the general form of the spot; at times the ends are blunt or rounded, again they are cigar shaped. One end has been seen rounded while the other was very much pointed. The sides are at times a little flattened, but are generally slightly rounded. On July 24 the south-side was curved or convex, while the north-side was somewhat flattened. It is sometimes long and lanky and then again it is fat and "chubby"—neither of these have been carried to extremes. Faint continuations, or trails, have been visible, sometimes from one end and then from the other. These have on several occasions been seen trailing from both ends at once, but are not always seen without close looking. At times the spot is a deep solid brick color; then again it is lightish red and pale. I have never, for certain, seen any detail on the surface of the spot, but I have sometimes thought that there *was* detail but just too indefinite for my aperture. The outline of the spot is always clean—no diffusion.

These observations are from notes and sketches which I have made this year with a 5-inch Byrne refractor.

E. E. BARNARD.

NASHVILLE, TENN., *December* 27, 1880.

NOTE.—The motions of the spots on Jupiter, in an article by me in "SCIENCE" No. 24, are referred to an assumed rotation period of 9h. 55m. 27.08s., which should have been stated in that article. E. E. B.

PENNULE'S COMET.

The following position of this comet was obtained by ring micrometer, on December 30, 1880, 7h. 01.2 m., Nashville m. t.:

R. A. 19h. 55m. 38.5s.

Dec. + 18° 52′ 39.6″

It is several minutes in diameter and very brightly condensed. E. E. BARNARD.

NASHVILLE, Tenn., Jan. 2, '81.

THE CAMBRIDGE OBSERVATORY.

The Annual Report of Prof. Pickering, Director of Harvard College Observatory, shows that the Observatory has been in a most prosperous condition during the past year, and if the same financial support is extended to it in the future that has been so generously offered in the past few years, it will be enabled to retain its place, inferior to no other Observatory in the country. The work carried on at the Cambridge Observatory consists of observations with the 15in. Equatorial, with the Meridian Circle and Meridian Photometer, together with the attendant reductions; and in the distribution of time-signals over the greater part of New England.

With the large equatorial, many important observations upon the satellites of Mars were made during the opposition of that planet. Employing the method of reducing the light of the planet, by colored glass (a method first used at this Observatory), the number of observed position angles of Deimos was 825; of Phobos, 278; and that of observed distances, 248. The probable errors of one setting were respectively 0.6°, 0.9° and 0.6″. Besides the micrometric work, many photometric observations were made, the results of which indicate that if we assume the satellites to have a capacity for reflecting sunlight equal to that of Mars itself, Deimos has a diameter of about six, and Phobos of about seven miles. The photometric observations upon the eclipses of Jupiter's satellites give reason to believe that by this method the determination of longitudes may be made as accurately as by occultations or lunar culminations. Measurements of the light of planetary nebulæ have been continued. The spectra of nebulæ are also observed through a direct vision prism placed between the object glass and eye-piece of the telescope. The planetary nebulæ retain their shape under these circumstances, obviously indicating that their light is monochromatic. The difference between monochromatic objects and ordinary stars is so marked when thus examined, that a method of detecting small nebulæ was at once suggested, and a comparatively short search revealed three such objects. The most remarkable discovery, however, was in the spectrum of the star Oeltzen 17681, R.A. 18h. 1m. 17s., Dec. −21° 1′, which shows that the light is concentrated in two points of the spectrum, one in the blue, the other in the yellow. A faint, continuous spectrum is also seen.

Between Sept. 24, 1879 and Nov. 1, 1880, observations were made with the Meridian Circle on 277 days, the work being confined to the determination of the absolute co-ordinates of 109 fundamental stars, in connection with which observations of the sun and of Polaris were made as often as possible. Up to Nov. 1, 1880, 183 observations of Polaris had been obtained, 131 of the Sun and 1760 of Fundamental Stars. To furnish the means of measuring the variation of the instrumental changes between one culmination of Polaris and the next, a collimator with focal length of 206 feet was constructed and has given excellent results.

A Meridian Photometer devised by Prof, Pickering has been used in continuing the measurement of the light of all stars visible to the naked eye between the north pole and the parallel of 30° south declination. Over 40,000 separate settings have already been made, and it is probable that the work will be completed in October next. The instrument, as its name implies, is mounted in the meridian and forms polarized images of the pole star and the star to be observed, which are brought to equality by turning a Nicol prism.

The time signals from the Observatory are distributed to the railroads and several prominent jewelers in Boston, and through the railroad companies to many of the neighboring towns. By the co-operation of the United States Signal Service Officer a time-ball is dropped in Boston at noon. The signals are also used in connection with those from the United States Naval Observatory, and the Allegheny City Observatory for the regulation of the New York time service.

During the past year, the second part of Volume XI of the Annals of the Observatory, containing a discussion of 25,000 photometric observations made with the great equatorial, and Volume XII containing the results of observations made by Prof. W. A. Rogers in 1874 and 1875 with the Meridian Circle have been completed and distributed, and six more volumes are in a more or less advanced state of preparation. W. C. W.

WASHINGTON, D. C.

ON THE THERMAL BALANCE.*

By Prof. S. P. Langley.

When the thermometer is not sufficiently sensitive for delicate investigation of radiant heat, scientific men have been accustomed, since the time of Melloni, to the use of the thermopile, an instrument which, employed in connection with the galvanometer, permits the making of numerous important measures. It has not been improved materially in the last fifty years. Meanwhile, many problems of both high theoretical and practical interest have arisen, which cannot be solved without a more sensitive and accurate instrument. One of these problems is the measurement of the distribution of radiant energy in a pure spectrum, when the rays have not passed through any prism. I could obtain no accurate results with the thermopile. I was forced to invent a more sensitive instrument for this special investigation, and, having done so, I believe it will be of general utility. The principle of the new apparatus has been applied by Dr. Siemens and others to other purposes. I spent several months in making it, as I hope, a useful working tool for the physicist and the physical astronomer. It is founded on the principle that, if a wire conveying an electric current be heated, less electricity flows through it than before. If two such wires, carrying equal currents from a powerful battery, meet in a recording apparatus (the galvanometer) the index of the instrument—pushed in two opposite ways by exactly equal forces—will remain at rest. If one current be diminished by warming ever so little the wire that conveys it, the other current causes the index to swing with a force due, not directly to the feeble heat which warmed the wire, but to the power of the battery which this feeble heat controls.

The application of this principle is thus made: Iron or steel is rolled into sheets of extreme thinness. I have succeeded in rolling sheets of steel made at the works of Miller & Parkin, Pittsburg, Penn., until it took 8000 of them to make the thickness of an inch. Of the platina sheets rolled at the United States Mint in Philadelphia, fifty laid one on another do not together equal the thickness of light tissue paper. Minute strips of these, 1-32 of an inch wide and ¼ of an inch long, were united so as to form a prominent part of the circuit, through which a part of a powerful battery passed to the galvanometer. Experiment proves that an almost inconceivably minute warming of a set of these strips reduced the passage of the electricity so as to produce very large indications on the registering instrument. I have in the course of my experiments thus far, found iron the most advantageous, though other metals are still under trial. The instrument thus formed is from ten to thirty times more sensitive than the most delicate thermopile; but this is almost a secondary advantage compared with its great precision and the readiness with which it is used. The thermopile is very slow in its action. This new instrument, the thermal-balance, takes up the heat and parts with it again in a single second. It is almost as prompt as the human eye itself.

With reference to its accuracy, experiments prove that the probable error of a single measurement made

* Read before the National Academy of Sciences, N. Y., 1880

with the instrument can be reduced to within 1 per cent. of the amount to be measured. It will register a change in the temperature of the strips just described, not exceeding 1-50,000 part of a Fahrenheit degree. When mounted in a reflecting telescope it will record the heat from the body of a man or other animal in an adjoining field, and can do so at great distances. It will do this equally well in the night, and may be said, in a certain sense, to give the power of seeing in the dark. A more valuable proof of its efficiency is shown in a series of measurements of the heat of the moon, made under varied circumstances, to guard against error, but each made in a few seconds. All these measurements show that the almost immeasurably minute amount of heat from the moon can be certainly measured by it, even with a common refracting telescope.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of SCIENCE :—

In a recent issue of "SCIENCE," "B. G. W." in a very instructive review of Marsh's monograph on the limbs of the *Sauranodon*, speaks of Darwin's hypothesis regarding *sexdigitism* in man, as reluctantly abandoned by that evolutionist, but as now standing some chances of rehabilitation owing to the discovery of *sexdigitism* as a normal feature of the extinct genus *Sauranodon.* Probably the reviewer has not met with a treatise, in in which a certain discovery of an embryonic peculiarity is detailed, and which explains not only the occurrence of *sexdigitism* but of *polydactylism* in man. As this treatise is in the hands of few comparative anatomists, I may refer to the facts here at some length. In figure 76 on page 137 of Schenk's *Lehrbuch der vergl. Embryologie der Wirbelthiere* (Vienna, 1874), is represented a section taken flatwise through the embryonic human paw. The chondrogenic elements of the mesoblast can be seen arranged in strands, indicating the metacarpophalangeal rays. A sixth ray seems very clearly present, and from some of the other rays lateral processes spring, which in the course of normal development become merged into the main ray, no doubt.

On this head, as well as some others related to the temporary presence of ancestral features in the extremities of the human embryo, I have written as follows in a series of lessons on embryology, published in the *St. Louis Clinical Record:*

At the points where the head and tail were respectively deflected from the trunk the peripheral protovertebrol masses are bulged out, as it were, and thus we have twa anterior and two posterior ill-marked eminences composed of mesoblast elements covered by the cutaneous epiblast. These are the anterior and posterior extremities. The posterior pair is the earliest to be discovered, but it is so rapidly outstripped in growth and development by the anterior extremities, that the belief has become current that the anterior are the first to appear, which is incorrect.

At the time when the hand has become demarcated from the forearm by the wrist constriction, the forearm has not yet become separated from the arm. And in like manner the foot is individualized before the leg and thigh are demarcated. The fingers are developed before the toes, and in both the hand and foot the digital segmentation is preceded by a stage in which there is a fold formed separating a main mass from the aggregate digital mass, and which persists in the adult.

If a surface section be made of an embryonic hand or foot before the digits are formed, we will find that the cell-strands which constitute the basis for each metacarpo-phalangeal ray are not five, as in the adult and developed fœtus, but are from seven to nine (at different periods) in number. This remarkable fact, discovered by my teacher, Prof. Schenk, of Vienna, points, in a manner, to the descent of the pentadactylous animals, to which man belongs, from the enaliosaurians or analogous groups of the jurassic and triassic periods of the earth's history whose fossilized remnants clearly show that they had seven or more fin rays.

To many, another and related fact will prove still more convincing in an evolutional point of view, although Schenk's observation is of more fundamental importance than the following to zoötomists:

Hensen, of Kiel, discovered that, in a ***human*** embryo of the seventh week, ***the fingers and toes are provided with claw-like appendages like the claws of carnivora,*** and that these structures are exfoliated to make way for the true nails. Further, he found plantar and palmar eminences like the ***foot-pads of the dog, cat and marsupial carnivores.****

E. C. SPITZKA.

NEW YORK Jan. 7, 1881.

BOOKS RECEIVED.

WAS MAN CREATED? By HENRY A. MOTT, JR., PH. D. Griswold and Company, New York.

The time is still distant when conclusions will be drawn on the subject of the Origin of Man and many other problems treated by the author of this book. Material is accumulating faster than it can be arranged, but in all probability, a thousand years hence we shall still be without sufficient data and be diligently searching for evidence.

The scientific man is not discouraged on this account, but is well content to work on, adding daily to the great store-house of knowledge, indifferent as to whether final results are arrived at in his own day or in the future.

There is, however, another class of persons in society, who, finding that certain scientific truths, which are undeniable, conflict with revealed religion, desire a more speedy solution of these questions.

Dr. Mott in his book attempts to outline a middle course for those who are forced by scientific discovery to renounce the Biblical teachings respecting the Origin of Man, by showing from a large number of authorities, that a belief in the dual existence of man may be held upon reasonable testimony.

Had Dr. Mott called his book "An Introduction to the Study of the Origin of Man and his Future Destiny," we think it would have been an appropriate title, and would have commanded a large class of readers who are unable to obtain the larger works consulted by the author; and the seventy-five illustrations, which are well selected, would have been of considerable service to such persons in grasping the subject which is naturally complicated to those who approach it for the first time.

DR. IRVINE, of Glasgow, recently exhibited and explained before the Mining Institute of Scotland, his new safety-lamp, which is constructed to emit a loud sound when an explosive mixture of gas and air enters it, and thus consequently indicates fire damp in colleries.

* Development of the Human Ovum Embryo, and Fœtus, *St. Louis Clinical Record*, (Lecture VIII.) June, 1880.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, JANUARY 15, 1881.

NOTICE TO SUBSCRIBERS.

We consider it due to those subscribers who have favored us with their subscriptions, previous to the publication of our club rates, that they should have the privileges of the list. They can therefore send us subscriptions for any or all of the publications named at the reduced double rates, less $4, the subscription price of "SCIENCE."

The lecture of Dr. George F. Beard on what he prefers to call "Mesmeric Trance," delivered this week before the New York Academy of Sciences, in the hal of the New York Academy of Medicine, received the close attention of an audience the majority of which, apparently, witnessed the experiments for the first time.

Dr. Beard described, briefly, the various forms of trance with which neurologists are familiar, and was supported by eight trance subjects, who exhibited manifestations of trance phenomena, to the equal satisfaction of the lecturer and his appreciative audience.

In regard to the genuineness of Dr. Beard's demonstrations we have no doubt that, substantially, they were *bona fide*, but it seemed apparent that the miserable objects who did duty on the occasion overacted their parts, and it may be even now an open question whether Dr. Beard or his audience was more imposed upon. Without intending to assert that an imposition was intended or practiced on the occasion, it is not difficult to show, probably, that many of the experiments might have been illusions. Two of the so-called patients were evidently trained performers, if not professional actors; if merely amateurs they surely missed their vocation. One of these patients could throw himself from an erect position to the stage, on his face, with the ease of an acrobat; the other declaimed Shakespeare at short notice, with the energy and persistence of a barrel organ. Other experiments also developed phenomena, which were not part of the programme. The boy who ate Cayenne pepper in a trance, believing it to be sugar, appeared to be not inconvenienced in the least when he returned to a normal condition. But still more remarkable was the behavior of the patient who was made "stone deaf." Dr. Beard shouted in vain to this man, a tuning fork was sounded, a bell rung, and even a pistol fired close to his devoted head, while the patient remained eloquently silent and apparently oblivious to all external sounds.

To de-hypnotize the subject, Dr. Beard, unmindful of the fact that he was supposed to be addressing a deaf person, said, in an ordinary tone of voice: "It's all right!" that being the usual phrase employed. To the surprise of many present, the patient (perhaps not desiring a *contretemps* to mar the performance) took the cue and quietly resumed his seat.

To a popular audience Dr. Beard's theories and experiments might have partaken of the character of a revelation, but we believe that nearly all our present knowledge of the subject dates from Braid's book on Hypnotism, published more than twenty years ago.

The policy of such public exhibitions may be well questioned; in Vienna they have been prohibited, and as no new truth can be gained or science advanced by repeating these experiments in such a manner, why make them the subject for an evening's amusement before a scientific society?

The patients selected perform their parts constantly, and thus become finally, perhaps unconsciously, more and more trained to elaborate their antics, so that, even admitting the genuineness of the performance, the experiments may be, at least so far, manufactured.

The subjects of Dr. Beard are chiefly selected from the nervous classes of our population, and although they may be willing to air their peculiarities before a fashionable audience, it would appear to be a charitable course to keep them from such public exhibitions which can result only in aggravating their morbid tendencies.

NEW YORK ACADEMY OF SCIENCES.

The Committee on Lectures announces that the remainder of the course will embrace five lectures, to be delivered at the new Hall of the Academy of Medicine, No. 12 West Thirty-first street, New York City, on the third Monday of each month.

These lectures are free to the public, but admission is strictly confined to those holding tickets, which may be obtained of D. S. Martin, 236 West Fourth street; W. P. Trowbridge, School of Mines, East Forty-ninth street, and Alex. A. Julien, School of Mines, East Forty-ninth street.

The programme includes the following lectures: January 17th, Respiration, by Dr. J. W. S. Arnold; February 21st, The Reptilian Affinities of Birds, by Professor Edward S. Morse; March 21, Sensation and Pain, by Dr. Charles Fayette Taylor; April 18th, Temple Architecture of the Tenth to the Fifteenth Century, by Professor George W. Plympton; May 10th, The Organic Elements, by Professor Albert R. Leeds.

HUNGER THE PRIMITIVE DESIRE.

By S. V. Clevenger, M. D.

A paper on Researches into the Life History of the Monads by W. H. Dallinger, F. R. M. S., and J. Drysdale, M. D., was read before the Royal Micrscopical Society, Dec. 3d, 1873, wherein fission of the Monad was described as being preceded by the absorption of one form by another. One Monad would fix on the sarcode of another and the substance of the lesser or under one would pass into the upper one. In about two hours the merest trace of the lower one was left and in four hours fission and multiplication of the larger monad began. A full description of this interesting phenomenon may be found in the *Monthly Microscopical Journal* (London), for October, 1877.

Professor Leidy has asserted that the Amœba is a cannibal, whereupon Mr. J. Michels in the *American Journal of Microscopy*, July, 1877, calls attention to Dallinger and Drysdale's contribution and draws therefrom the inference that each cannibalistic act of the Amœba is a reproductive one, or copulative, if the term is admissible, The editor (Dr. Henry Lawson), of the English journal, Oct., 1877, agrees with Michels.

Among the numerous speculations upon the origin of the sexual appetite, such as Maudsley's altruistic conclusion, which always seemed to me to be far-fetched, I have encountered none that referred its derivation to *hunger*. At first glance such a suggestion seems ludicrous enough, but a little consideration will show that in thus fusing two desires we have still to get at the meaning and derivation of the primary one—desire for food.

The cannibalistic Amœba may, as Dallinger's Monad certainly does, impregnate itself by eating its own kind, and we have innumerable instances among Algæ and Protozoa of this sexual fusion appearing very much like ingestion. Crabs have been seen to confuse the two desires by actually eating portions of each other while copulating, and in a recent number of the *Scientific American*, a Texan details the *Mantis religiosa* female eating off the head of the male Mantis during conjugation. Some of the female Arachnidæ find it necessary to finish the marital repast by devouring the male, who tries to scamper away from his fate. The bitings and even the embrace of the higher animals appears to have reference to this derivation. It is a physiological fact that association often transfers an instinct in an apparently outrageous manner. With quadrupeds it is undoubtedly olfaction that is most closely related to sexual desire and its reflexes, but not so in man. Ferrier diligently searches the region of the temporal lobe near its connection with the olfactory nerve for the seat of sexuality, but with the diminished importance of the smelling sense in man the faculty of sight has grown to vicarate olfaction; certainly the "lust of the eyes" is greater than that of other special sense organs among Bimana.

In all animal life multiplication proceeds from growth, and until a certain stage of growth, puberty, is reached, reproduction does not occur. The complementary nature of growth and reproduction is observable in the large size attained by some animals after castration. Could we stop the division of an Amœba a comparable increase in size would be effected. The grotesqueness of these views is due to their novelty, not to their being unjustifiable.

While it would thus seem apparent that a primeval origin for both ingestive and sexual desire existed, and that each is a true hunger, the one being repressible and in higher animal life being subjected to more control than the other, the question then presents itself: What is hunger? It requires but little reflection to convince one of its potency in determining the destinies of nations and individuals, and what a stimulus it is in animated creation. It seems likely that it has its origin in the atomic affinities of inanimate nature, a view monistic enough to please Haeckel and Tyndall.

NOTES ON THE ANATOMY OF THE ENCEPHALON, NOTABLY OF THE GREAT GANGLIA.

By Edward C. Spitzka, M. D.

The anatomy of no portion of the brain is so obscure and so imperfectly known as that of the so-called Thalamus opticus. One of the first requisites to a comprehension of its relations is the establishment of a proper nomenclature, and the point to start from is the very name under which the great ganglionic mass is known. Since it is not exclusively or even in the main connected with the optic tracts in any animal or man, and, indeed, is in the lower sauropsidæ and amphibians not connected with them at all, the affix *opticus* should be dropped, and the first word involving that very uncompromising conception of an elevation at the ventricular floor may be retained: *Thalamus.*

The current conception that the Thalamus is an elevation at the floor of the *lateral* ventricle is incorrect. One of our leading comparative anatomists will shortly review this question, and it will therefore be but necessary for me to refer to the matter.

In the cat's brain it can be clearly seen, that (aside from membranous separations) the great mass of the Thalamus is excluded from the cavity of the lateral ventricle by the fusion of the lateral edge of the fornix with the corpus striatum, or rather with the ependyma of that ganglion. Consequently, the two thalami are included in the third ventricle, which cavity on cross section resembles an upright T, whose vertical branch descends between the thalami, as a deep ditch, the *vulva cerebri* of the old anatomists.[1]

Luys, who was unfortunately wedded to certain physiological prejudices as to the function of the thalamic centres, restricted the term *Thalamus* to the most external mass. Meynert called all the centres in the aggregate by that term as a collective designation. He excluded, however, that gray mass which lines the sides of the vertical slit of the third ventricle.

Now, the third ventricle, as shown by Hadlich and Wilder, extends over the entire thalami; it would be, therefore, incorrect to limit the designation "central tubular gray of the third ventricle" to that portion only which lines the vertical slit. Either this latter designation should be extended to the entire thalamic masses or the term thalamus should be extended to the so-called central tubular gray.

Thus interpreted there would be, strictly speaking, but a single thalamus, consisting of two main masses, and a commissural part. The commissure is double. The thalami are primitively united by the lower of these commissures, which I propose to term "basilar commissure."[2] Secondarily, and only in animals above marsupials (as far as I am aware), do we find another commissure produced at an advanced period of embryonic development by apposition of the main masses. This is the so-called middle commissure of the brain, the *commissura grisea, c. mollis.* I should consider the least ambiguous designation, "the *thalamic fusion.*"

In a manner similar to that which separates the caudate and lenticular nuclei from each other, and which divides the latter into subsidiary "articuli," the chief mass of each thalamus is separated into an inner and outer zone. The zones are separated from each other by

[1] The corresponding *penis cerebri* of the same anatomists has, by more fastidious colleagues, been rebaptized *pinus cerebri* and later *pineal gland*, now known as the *epiphysis cerebri*.

[2] Continuous in front with the *loci perforati antici*, behind with the infundibulum. Atrophic over the chiasm, it exhibits a set of transverse fibres and gray substance elsewhere.

a white intercalation, and especially the outer zone (also in part the inner) presents a beautiful alternation of gray and white laminæ.[3]

These two gray zones constitute the fundamental demarcation of the thalamus; they may be termed *zona grisea medialis* and *zona grisea lateralis*. In animals above the rank of marsupials we find added a round nodular mass, distinctly prominent at the ventricular floor, which lies anteriorly, while in still higher groups a second nodular prominence develops posteriorly. The latter is known as the posterior tubercle or pulvinarium, the former as the *anterior* or *snperior tubercle*. The former designation seems the best to me, for although what I call the undifferentiated parent mass of the thalami is visible in sections anterior to those in which the anterior tubercle is reached, yet the latter, which I propose to term the *anterior nodule* of the thalamus, is the first differentiated centre reached. In man the *zona grisea medialis* is faintly seen before the anterior nodule is reached, but the anterior nodule reaches its main development before the zones do, and is absent where these are most prominent. In the carnivora generally, the anterior nodule projects far in advance of the zones. In these animals, too, a more complex arrangement of this nodule is found than in man, inasmuch as the anterior part of the internal slope of the thalamus shows several elevations absent in the human thalamus.

The *zona grisea medialis* appears pretty equally diffused and exhibits its lamination evenly both in front and in the middle of its course. The same applies to the human brain for the *zona grisea lateralis*. In the cat,[4] however, the anterior part of the external zone appears as a beautiful round compact ganglionic mass, protruding boldly into the internal capsule, and which acquires the characteristic lamination only in posterior planes.

It is interesting to note that the ganglionic matter of the thalamus is continuous with that of the ventricular nucleus of the corpus striatum (nucleus caudatus). Indirectly it is connected with the extra-ventricular nucleus, through that great common basilar gray mass, which is the *rendezvous*, as it were, of all the gray categories of the forebrain.[5]

In an earlier publication (Architecture and Mechanism of the Brain—Journal of Mental and Nervous Diseases, 1879), I have called attention to the fact that the ventricular nucleus of the corpus striatum is the representative of the primordial cerebral gray, inasmuch as the nerve cells of the embryonic and lower amphibian hemisphere are concentrated immediately subjacent to the ependyma of the latter ventricle. The majority of these cells are crowded away from the ventricular floor by the white substance developed in higher animals, and only a portion of the primitive gray remains subependymal. This is precisely what constitutes the corpus striatum. Now the corpus striatum actually *lines* the ventricle; it not only lies at its floor! Any section transversely to the cerebral axis and striking the forepart of the lateral ventricle in the Hippopotamus, Horse, Dog or Cat, will show that an attenuated part of the corpus striatum is continued around *over* the ventricle, and constitutes a greater part of its roof.

A similar comparative study shows that the nucleus lenticularis is also a subcortical development, that is, it results from the individualization of a gray mass originally continuous with the cortex, by means of an irruption of white masses. These at first separate fasciculi (as in the dog) in higher animals coalesce to constitute the external capsule. The segmentation of the lenticular nucleus into three distinct *articuli* so characteristic of the human brain, is not found in the carnivora; only the outer articulus is demarcated, and that but imperfectly.

In the carnivora the *laminae medullares* or white streaks of the lenticular nucleus are conspicuously absent in the anterior half of that ganglion; in its posterior half they appear and they rapidly increase in bulk as we proceed backwards, so that in planes where the human lenticular nucleus is still quite massive, we have in the dog only slight ganglionic masses intercalated between the fibre tracts. The *claustrum* is, in the carnivora, not the thin expanded lamina found in man, but a low and massive accumulation, hardly separated from the cortex of the Island of Reil. This fact strengthens Meynert's view that the claustrum is but an individualized cortical layer.

In conclusion I would mention as an isolated fact, and disconnected from the main subjects dealt with in these notes, that the anterior pyramids of the brain of the large Ceylon fruit bat (Pteropus fuliginosus) undergo a superficial decussation, as patent, and more so, as that of the optic chiasm. The pyramidal tract after decussating is continued as a distinct fasciculus on the lateral aspect of the medulla oblongata. In the same brain the fibres of the fornix can be clearly seen to terminate in the thalamus without descending to the base of the brain. Whether this applies to the whole of that tract, I am not able to say.

I would also note that in the brain of a large Ara (*Ara ararauna*) obtained from the Superintendent of the Central Park Zoological Gardens, Mr. W. A. Conklin, I found what appeared to be a thin commissure uniting the two cerebral hemispheres in their posterior half. This (commissure! if the observation was correct) was not, like the Corpus callosum, a connection between the internal white matter of both hemispheres, but merely a union of the superficial white, which in lower animals is well-developed outside of the cortical gray.

In the *carnivora the Ganglion* of Soemmering (the *Substantia nigra* in the human brain) is continuous with the innermost part of the lenticular nucleus. This fact strengthens Meynert's proposition, that the Ganglion of Soemmering, like the caudate and lenticular nuclei, should be considered as parts of one system, whose ganglia are connected with the fibres of the *pes pedunculi*.

In the elephant, whose brain, both in its mass, the preponderance of the hemispheres, and the concealment from view of the so-called "trapezium," takes a high rank as regards the grade of development, I had the opportunity to make and examine transverse microscopic sections from the Pons Varolii. The remarkable discovery was made that the descending (longitudinal) fibres of the Pons are wanting. Nothing but transverse fasciculi are seen in the field. Since the former fibres constitute part of the pyramidal tract, it follows that the tract of the voluntary impulses, the "will-tract," must take another course in the elephant, one which may be considered aberrant; for in all other placental animals so far examined by myself, the pyramidal tract runs through the Pons Varolii, as in man.

---

[3] And yet the latest pretended description of these Ganglia, admitted, notwithstanding numberless glaring errors, into a journal of the standing of "Brain" (that by Dalton), has the Thalamus "homogenous."

[4] As seen in a series of transverse sections prepared by Dr. Graeme Hammond.

[5] Here meet the olfactory gray, the cortex, the *basis capitis nuclei caudati*, the *nucleus lenticularis*, the *claustrum*, the thalamic axial gray, etc., etc.

ON WALDIVINE.—Waldivine, $C_{36}H_{24}O_{20}$, is a neutral principle, without rotatory power, very sparingly soluble in cold water, freely soluble in chloroform, insoluble in ether, and remarkable for the ease with which it is decomposed by alkalies.

CERTAIN OPTICAL AND VISUAL PHENOMENA—If the flame of a lamp is viewed through a narrow slit, the lustre of the flame and the effects of diffraction vary much according as the slit is vertical or horizontal, the light being much more considerable in the latter case.—M. TREVE.

EFFECT OF PRESSURE ON THE FUSION POINT.

Dr. Carnelly recently read a paper before the Chemical Society of London, in which he thus explains the device which he has adopted in order to secure and maintain a vacuum in a case of ice. For the success of the experiment the tension must be below 5 millimetres. The apparatus consists of a wide glass tube ¾ inch in diameter, and about 5 to 6 feet high. This is placed in a vertical position, and is connected at its upper end with a strong glass flask placed horizontally, and surrounded with a freezing mixture. The apparatus having been inverted and filled with mercury, the lower end of the tube is closed with the thumb, and placed under the surface of a layer of mercury about 10 inches deep. On withdrawing the thumb the mercury sinks in the tube to the barometric height, and a large Torricellian vacuum is obtained, which is surrounded, as far as the flask is concerned, with a freezing-mixture. A small quantity of boiled water is now introduced, which rises to the top of the mercurial column, and surrounds the bulb of a thermometer suspended inside of the tube. The water is then frozen, and the depth of the layer of mercury in which the tube stands reduced to about 3 ins.; in consequence the mercury in the tube sinks, and leaves a detached column of ice with the thermometer bulb in its centre. This column acts as a cork, shutting off the large vacuous space above from the small vacuum below. By carefully heating the tube the ice is melted round the circumference of the plug, and a fine annular opening is made between the ice and the inside of the glass tube. This restores the communication between the upper and lower portion of the vacuum. As soon as this is effected, any aqueous vapor which is formed is at once condensed by the freezing-mixture, and the vacuum is kept intact. Under these circumstances the author has made the ice so hot that the thermometer in the centre of the cylinder stood at 180° C. before the ice melted. In the experiment shown to the Society the thermometer only rose to 30° C. when the cylinder (which was too large and therefore too heavy) dropped off the thermometer. To prove that the ice was really hot Dr. Carnelly has contrived and carried out some experiments, in which the cylinder of hot ice was dropped into a small calorimeter filled with water; the temperature rose when the ice was introduced, whereas if ordinary ice it would of course have been lowered. He then showed two experiments with camphor and mercuric chloride, which were perfectly successful. The camphor was contained in a glass tube closed at one end and connected at the other with a Sprengel pump. On heating the tube the camphor melted, but on starting the Sprengel pump the camphor, as the pressure decreased, solidified, though the heating was continuous. The mercuric chloride was similarly raised many degrees above its ordinary melting-point, when kept under diminished pressure, without liquefying; but on allowing the atmospheric pressure to enter, by cutting the tube, the solid mass immediately melted and began to boil.

THE PHILOSOPHICAL SOCIETY OF WASHINGTON.

We are informed by Professor Cleveland Abbe that the following are the newly elected officers of the Philosophical Society of Washington: President, Dr. J. J. Woodward; Vice-Presidents, Dr. G. K. Barnes, J. E. Hilgard, J. C. Welling, William Taylor; Secretaries, J. N. Gill, C. E. Dutton; Treasurer, Cleveland Abbe.

HYPNOTISM.

A writer in the *Medical Record* sums up the result of his experiences of Hypnotism and its phenomena as follows:

First. Impressions cannot be communicated to individuals in the hypnotic condition, except through the external senses. The mind of the operator cannot influence that of the subject by a purely mental effort. He must either speak, write, or gesticulate to convey his ideas.

Second. Remembrance of what has passed, during the hypnotic state, in the mind of the subject, is very slight, but if he is told to remember any particular thing while so affected, he will recollect it when he awakens.

Third. Although I pursued the method used by others, I am satisfied that the employment of any means that will induce a temporary abstraction of the mind is all that is required to induce the peculiar condition.

Fourth. Although the subjects seem to be entirely oblivious to all that is going on, they are not perfectly so. In the case of a young lady, who was told that she was a bird, and thereupon commenced to hop, her dress became disarranged, and, although continuing to hop like a bird, she was careful to keep her dress in its proper condition.

Fifth. It is not necessary that the operator nor the one operated upon believe in the truth of hypnotism, or the success of the trial. If the necessary conditions are complied with the effect will follow. One case mentioned above proves this to be true.

All the strange psychical conditions under the names of hypnotism, magnetism, braidism, mesmerism, trance, somnambulism, ecstacy, etc., come under the same category, and I believe that clairvoyance and spiritualism can be included in the list.

As far as I have seen, I have never observed contraction of muscles, areas of hyperæsthesia, or other disorder of sensibility, or any unnatural condition or action of any part of the body in the persons affected, unless the operator should direct their attention to themselves by speaking or motioning to them; for example, he would indicate that their faces were away, that their arms or fingers were stiff, or that they had a pain in the head, back, or some other part. In such a case what was told them would be the basis on which they would feel or act.

If I should venture an explanation, or more properly a description of the phenomena of hypnotism, I would say that they resulted from a suspension of function of the centre for ideas in the brain of the subject, and also of his will, while the infra-cortical ganglia remain free to act from a reflex excitation imparted by the voice, gestures, or manners of the operator.

THE HAMMOND PRIZE.

The American Neurological Association offers a prize of five hundred dollars, to be known as the "William A. Hammond Prize," and to be awarded, at the meeting in June, 1882, to the author of the best essay on the *Functions of the Thalamus in Man.* The conditions under which the prize is to be awarded are as follows: 1. The prize is open to competitors of all nationalities. 2. The essays are to be based upon original observations and experiments on man and the lower animals. 3. The competing essays must be written in the English, French, or German language; if in the last, the manuscript is to be in the Italian handwriting. 4. Essays are to be sent (postage prepaid) to the Secretary of the Prize Committee, Dr. E. C. Seguin, No. 41 West Twentieth street, New York City, on or before February 1, 1882; each essay to be marked by a distinctive device or motto, and accompanied by a sealed envelope bearing the same device or motto, and containing the author's visiting card. 5. The

successful essay will be the property of the Association, which will assume the care of its publication. 6. Any intimation tending to reveal the authorship of any of the essays submitted, whether directly or indirectly conveyed to the Committee or to any member thereof, shall exclude the essay from competition. 7. The award of the prize will be announced by the undersigned Committee; and will be publicly declared by the President of the Association at the meeting in June, 1882. 8. The amount of the prize will be given to the successful competitor in gold coin of the United States, or, if he prefer it, in the shape of a gold medal bearing a suitable device and inscription.

Signed, F. T. MILES, M.D., *Baltimore.*
J. S. JEWELL, M.D., *Chicago.*
E. C. SEGUIN, M.D., *New York.*

CHESAPEAKE ZOOLOGICAL LABORATORY.

Dr. W. K. Brooks, Director of the Chesapeake Zoological Laboratory, established under the auspices of the the Johns Hopkins University, in his report for 1880 states: By the liberality of the Trustees, it was possible to spend a much longer period than hitherto at the seaside, and provided with a more liberal outfit, including a steam launch which was built, for our use in the last spring, at Bristol, R. I., and has proved a very efficient auxiliary. The necessary books, dredges, and other instruments were also provided by the University. In addition to the opportunities afforded to three of the members of our own academic staff, three other gentlemen, devoted to the study of Zoology, were invited to avail themselves of the scientific facilities of the station.

The laboratory was opened at Beaufort, N. C., on April 23, 1880, and closed on September 30, after a session of twenty-three weeks. It was supplied with working accommodations for six investigators, and the facilities which it afforded were used by the following six persons: W. K. BROOKS, PH. D., Director; K. MITSUKURI, PH. B., Fellow in Biology; E. B. WILSON, PH. B., Fellow in Biology; F. W. KING, A. M., Professor of Natural Science, Wisconsin State Normal School; H. C. EVARTS, M. D., Academy of Natural Sciences, Philadelphia; H. F. OSBORNE, PH. D. Fellow of the College of New Jersey.

Beaufort was selected for our third season's work because it is the nearest accessible town, south of Baltimore, which is favorably situated for zoological study. The advantages of a location in a town are well shown by the fact that the expenses of a session of twenty-three weeks this year were considerably less than those of a ten weeks session the year before.

The scientific advantages of Beaufort are very great; the most important is the great difference between its fauna and that of our northern Atlantic coast.

The configuration of our coast line is such that Cape Hatteras, the most projecting point south of New York, deflects the warm water of the Gulf Stream away from the coast, and thus forms an abrupt barrier between a cold northern coast and a warm southern one. The fauna north of this barrier passes gradually into that of southern New England, while the fauna south of this barrier passes without any abrupt change into that of Florida, but the northern fauna is sharply separated by Cape Hatteras from the southern.

As the laboratory of the U. S. Fish Commission and Mr. Agassiz's laboratory at Newport afford opportunites for work upon the northern fauna, it seemed best for us to select a point south of Cape Hatteras in order to study the southern fauna with the same advantages, and as Beaufort is the only town near the Cape which can be reached without difficulty, it was chosen as the best place for the laboratory.

The situation of this town is exceptionally favorable for zoölogical work, for the surrounding waters present such a diversity of conditions that the fauna is unusually rich and varied.

Close to the town there are large sand bars, bare for miles at low tide, and abounding in animal life. From these we could collect an unfailing supply of *Amphioxus*, *Renilla*; *Limulus*, *Balanoglosus*, Sea Urchins, and a great variety of Molluscs and Crustacea.

The mud flats furnished us with another fauna, and yielded a great variety of Annelids, a new set of species of Crustacea and Molluscs, Gephyreans, Echinoderms, and Polyps. The large salt marshes gave us a third fauna, and a short distance inland large swamps of brackish and fresh water furnished still other conditions of life.

As the town is situated at the point where Gore Sound connects Pamlico Sound with Bogue Sound we were within easy reach of a continuous sheet of landlocked salt water more than a hundred miles long, and these Sounds furnished still another collecting and dredging ground, abounding in Corals, Gorgonias, Ascidians, Star Fish, Sea Urchins, and a new set of Molluscs and Crustacea.

As most of the shores are flat and sandy, those animals which live upon a sandy bottom are much more abundant than those which attach themselves to solid bodies, but the stone breakwaters at Fort Macon, the wharves at Beaufort and Morehead City, and the large oyster beds which are found in the sounds furnish a proper habitat for many fixed animals, and yielded us a rich supply of Hydroids, Corals, Ascidians, Sea Anemones, Sponges, Cirrhipeds, &c. The ocean beach, within a short distance of the town, furnished still another fauna, and a soil of three miles from the laboratory carried us to a good locality for ocean dredging.

The greatest advantage of the locality is the richness of its pelagic fauna. There are very few points upon land which are so situated that the surface animals of mid-ocean can be procured in abundance for laboratory work, and as careful work is very difficult on shipboard, a laboratory which can be furnished with a good supply of living pelagic animals presents opportunities for work in an extremely interesting and almost new field.

The Gulf Stream is constantly sweeping these animals northwards along the North Carolina coast, and as the tide sets in through Beaufort Inlet into the Sounds the floating animals are carried with it. Such oceanic animals as *Physalia* and *Porpita* were frequently thrown, uninjured and in perfect health, upon the beach within twenty feet of the laboratory, and during the season we found nearly all the Siphonophoræ which are known to occur upon our Atlantic coast.

With all these advantages we enjoyed a mild and uniform climate which enabled us to work in perfect comfort during the hottest months of summer.

The zoölogical resources of Beaufort have not escaped the attention of American naturalists, and there are few places upon our coast, outside of New England, where more zoölogical work has been done. In 1860, Drs. Stimpson and Gill spent a season in dredging and collecting in the vicinity of Beaufort, Cape Lookout and Cape Hatteras, and an account of their work was published in *The American Journal of Science.* Dr. Coues, who was stationed at Fort Macon during the war, occupied himself for two years in collecting the animals which are found here, and he published a series of papers on the "Natural Histsry of Fort Macon and Vicinity" in the Proceedings of the Academy of Natural Sciences of Philadelphia.

These papers, which were continued by Dr. Yarrow, contain copious and valuable notes on the habits and distribution of the animals which were observed, and we found them a great help to us. These two naturalists found four hundred and eighty species of animals in the vicinity of Beaufort. Of these four hundred and eighty, two hundred and ninety-eight are vertebrates, and one

hundred and eighty-two are invertebrates. Of the vertebrates twenty-four are mammals, one hundred and thirty-three are birds, twenty-seven are reptiles, six batrachians, ninety-seven fishes and eleven selachians. Of the invertebrates, one hundred and forty-seven are molluscs, twenty-one are crustaceans. The list of vertebrates is very nearly exhaustive, and we made no additions to it, but the list of invertebrates is obviously very imperfect, and, although we made no attempt to tabulate the species which we observed, there would be no difficulty in enlarging the list twenty or thirty fold.

Among other naturalists who have spent more or less time at Beaufort, I may mention Professor L. Agassiz, Professor E. S. Morse, Dr. A. S. Packard, Professor Webster, and Professor D. S. Jordan. Professor Morse procured most of the material for his well known paper on the Systematic Position of the Brachiopoda on the sand bars in Beaufort Inlet.

I will now attempt to give a very short statement of some of the leading points in our own summer's work. Much of our time was spent in studying the development of the Crustacea, since this is one of the most important fields for original work upon our southern coast. The supply of mat·rial is almost nexhaustible, and would employ a number of students for imany years. The life history of the Crustacea is of great interest in itself, and the recent species are so numerous and diversified that there is no group of animals better adapted for studying the general laws of embryonic development in their relation to the evolution of the group.

These considerations have led us to devote especial attention to this group during this and the preceding seasons. One of the published results of the first season's work was an illustrated account of the metamorphosis of *Squilla*, a representative of a somewhat aberrant group of Crustacea. During the second season, a member of our party, Professor Birge, made a very thorough study of the development of *Panapæus*, one of our crabs, and the account of his observations, with drawings, was ready for publication several months ago. At Beaufort, we spent most of our time upon this subject, and figured more than eight hundred points in the development of various Crustacea.

Among these, I wish to call especial attention to our observations upon the development of the Sergestidae; the least specialized of the stalk-eyed Crustacea. This very peculiar group was not known to occur upon our coast until we found a few specimens of one genus at Fort Wool, and the same genus —*Lucifer*—in great abundance at Beaufort, associated with another genus which is also new to North America. As nothing whatever was known of the development of *Lucifer*, we made every effort to obtain the eggs and young, and after four months of almost fruitless labor we finally succeeded in finding all the stages of the metamorphosis, and figured them in a complete series of ninety-nine drawings. We also obtained a somewhat less complete series of figures of stages in the life history of the second Sergestid.

Our only motive in this work was the desire to fill a gap in our knowledge of crustacean development, by supplying the life history of a very interesting group of animals, but the result was found to have a very unexpected value, since it contributes to the discussion of a number of problems in general embryology and morphology, and is the most significant crustacean life history which has ever been studied.

The following are some of the more important points:

The egg undergoes total regular segmentation.

There is no food yolk, and cleavage goes quite through the egg.

There is a true segmentation cavity.

Segmentation is rhythmical.

There is an invaginate gastrula.

The larva leaves the egg as a Nauplius, and passes through a protozoan stage, and a schizopod stage.

The fifth thoracic segments and appendages are entirely wanting at all stages of development.

Another interesting group which was studied is the Porcellanidae, the least specialized of the true crabs. The adults of our American species are almost restricted to our southern waters, although the swimming larvæ are carried north by the Gulf Stream. Within the last two years two northern naturalists have studied these floating embryos upon the south coast of New England, but as they were working upon stragglers so far from home their accounts are incomplete and somewhat contradictory. Our advantages at Beaufort enabled us to contribute towards the solution of this confused subject by raising one species of *Porcellana* from the egg.

We also raised six other species of crabs from the egg, and made drawings of the more important stages of development. One of the species which was thus studied is the edible crab. Its metamorphosis has never been figured, and although it presents no unusual features, its economic importance gives value to exact knowledge of its life history.

Mr. Wilson also studied the development of one species of Pycnogonida, a group of very peculiar Arthropods, distantly related to the spiders. As he has paid especial attention to the systematic study of this group, and is now engaged in describing the Pycnogonids collected in the Gulf Stream by Mr. Agassiz, the opportunity to study them alive in the laboratory has been a great advantage to him.

Another important investigation is the study, by Mr. Wilson, of the embryology of the marine Annelids. Although the representatives of this large group are abundant and widely distributed, little was known of the early stages of their development until he procured the eggs of several species and studied them at Beaufort. This investigation has shown, among other things, that the accepted division of Annelids into two great groups, the Oligochæta and Polychæta, is not a natural method of classification. The work upon the development of marine Annelids was supplementary to an investigation which Mr. Wilson carried on last spring at Baltimore, and which he will continue this winter, upon the development of land and fresh water Annelids.

As much time as possible was given this season to the study of the hydroids and jelly-fish of Beaufort. The life histories of several of them were investigated, a thorough anatomical study of some of the most important forms was carried on, and nearly two hundred drawings were made. It is almost impossible to complete a study of this kind in a single season, but if one or two more summers can be given to the work, we have every reason to hope for valuable results; for although the North Carolina coast is the home of many species which are only found as stragglers upon our northern coast, and of other species which are not known to occur anywhere else, and of some genera and families which are new to the North American coast, this field has suffered almost total neglect.

Nearly three months of the time of two members of our party, Mitsukuri and Wilson, were given to the study of the habits, anatomy and development of *Renilla*, a compound Polyp very much like that which forms the precious coral, but soft and without a stony skeleton. The animals which form the community are so intimately bound together that the community, as a whole, has a well marked individuality distinct from that of the separate animals which compose it. The compound individuality of *Renilla* is quite rudimentary as compared with that of a Siphonophore, and as there is no trace of it in the closely allied Gorgonias, it furnishes an excellent field for studying the incipient stages in the formation of a compound organism by the union and specialization of a community of independent simple organisms. With this end in view the anatomy of the fully developed community was care-

fully studied, and the formation of a community was traced by rearing a simple solitary embryo in an aquarium until a perfect community has been developed from it by budding. During the process of development the law of growth by which the characteristics of the compound organism are brought about was clearly exhibited, and it is fully illustrated by nearly one hundred drawings.

One of the most interesting results of our work is the explanation, by Mr. Wilson, of the origin of the metamorphosis of the larva of *Phoronis*, a small Gephyrean worm which lives in a tube. Several of the most noted embryologists of Europe have studied the development of *Phoronis*, and our knowledge of its life history is due to their combined labors. Last summer Mr. Wilson reviewed the subject, and added some important points, and during the present season he has shown by the comparison of a great number of allied forms, that the very peculiar metamorphosis admits of an extremely simple explanation. The adult is sedentary and confined to its sand tube, while the larva is a swimming animal totally different in structure. The change from the larva to the adult is very rapid and violent. It occupies only a few minutes, and during the change the larva becomes turned wrong side out, so that what was internal is external. Mr. Wilson's comparison shows that *Phronis* was originally a free animal, and that the structural peculiarities which fit the adult for sedentary life in a tube are of recent acquisition. The larva has, however, retained its ancestral adaptation to a swimming life in order to provide for the distribution of the species. There must have been a time, in the evolution of the species, when the adult was imperfectly adapted to a sedentary life, and also imperfectly adapted to a swimming life, and if the development of the individual were a perfect recapitulation of all the stages in the evolution of the species, we should have, between the swimming larva and the sedentary adult, a stage of development during which the adaptation is not quite perfect for either mode of life. It is clearly an advantage for the animal to pass through this stage as quickly as possible, or to escape it altogether. The peculiar metamorphosis enables the larva to remain perfectly adapted to a locomotor life until the occurrence of the sudden change which fits it for life in a tube, and Mr. Wilson has pointed out the manner in which the metamorphosis has been acquired in order to bridge over the period of imperfect specialization. This explanation is somewhat similar to that which Lubbock has given of the origin of the metamorphosis of insects, and we may hope that the same method of investigation will throw light upon the significance of other remarkable instances of metamorphosis in the Invertebrates.

THE MATERIALISTIC ORIGIN OF THE SEXES.

By Andrew Dewar.

Materialism is yet in its infancy. Born of human learning, weaned in scientific research, and cradled in the toleration of an enlightened civilization, its advent marks an epoch in the history of humanity. Should there be fearful shadows in its progress, where loiter grim doubts and gloomy forebodings, these are only consequent to its youth, and the necessary result of the light from a sun whose slanting rays only reach us. But even as the noonday sun chases away the shadows in its splendor, so we are assured that no doctrine in these enlightened days will ever be accepted which does not in its maturity shine on the human race for true knowledge and good.

"All knowledge is our province," said Bacon, and we would be less than men if any phenomenon in nature was considered inscrutable by us, the highest outcome of Nature. Thinking thus, one of the most curious problems is that of the sexes; and the value of the doctrine of Materialism is apparent when we come to question its cause, for no natural law professes even to offer an hypothesis on the subject.

It may here be asked, what is the doctrine of Materialism? As enunciated by the most advanced physicists, it is that "Matter contains within itself the promise and potency of every form and quality of life." This, it will be correctly said, is only a statement, not a *cause*—an assumption that requires proof, not a proposition of fact which may be demonstrated with the facility of a problem in Euclid. Granted; but it will be admitted that if we can show how the sexes originate from matter and its inherent properties, Materialism must be more than an assertion. This without further introduction we now propose to discuss.

Taking matter and its properties as the only foundation we can build on with safety, we ask What is Matter?

After long years of experiment and failure we answer this question with a firm assurance in several things:

First. The Indestructibility of Matter. This involves both the eternity of matter and the eternity of the properties of matter. Nothing exists outside of matter. Nothing but matter and its properties exist. Nothing can be taken from matter, nothing can be added to it. Whatever properties matter may have had, matter must have now; and, *vice versa*, whatever properties matter has now, matter has always had.

Secondly. Matter is composed of elements of which sixty-four are known. Everything consists of those elements, their combinations, changes, and properties. Whatever form they take now, under similar circumstances they would either in the past or future also assume.

This is the foundation of Materialism, and so far as it goes is perfectly clear and logical. Presuming that no force exists outside of matter, the *properties of matter* must account for every phenomenon in matter, and should they fail the premises fail also, and the fact is made certain that a force exists outside of matter, and *ergo* that Materialism is dead.

What, then, are the properties of Matter?

Here there is confusion and disagreement. Gravitation, cohesion, and chemical attraction are the three forces which have been popularly supposed to control matter; but when Huxley pertinently asked what these forces are, he found them not forces at all, but mere names or effects of a cause or causes unknown. Even Evolution, from which so much was expected and preached, has fallen into disgrace, and proved to be no force or cause either, but merely an "orderly sequence of phenomena" from some cause or causes unknown. How are we, then, to discover those unknown causes? If Materialism be true, they must exist; but Materialism cannot be maintained as a doctrine until we show that they do exist and what they are.

We are thus led back to our premises again—to matter and the elements—and we say, according to materialistic doctrine, if sex exists in matter now, sex must always have existed. Consequently, if matter was once a sheer chaos, or, as the most daring of physicists assert, a universal firemist, then sex in some form or another existed in that chaos or in that mist. As, assuredly, it did not exist in the form of any kind of life we are acquainted with, we are led to ask *if matter does not contain within itself some inherent sexual or dual qualities*. If it does, Materialism is alive; if not, Materialism is dead.

Matter is composed of sixty-four elements, more or less; are these elements all alike in kind, or can we trace a sex or duality in them? Fortunately for our doctrine we can. Although stated by eminent chemists to be of no importance, and made "solely for the sake of simplicity," the elements have long been divided into metallic and non-metallic classes. All the elements belong either

to one class or the other. So far success seems to favor us. Doubt is the mainspring of progress, and this doubting of a fact which has long been maintained to be of *no importance* may be the key to open up unknown vistas of research.

It will, however, be conceded in a matter of no importportance that this dual classification may be incorrect. This we believe to be the case, for one very important element—hydrogen—is given in every classification among the non-metallic elements, while the element itself is admitted to be metallic; a strange and incomprehensible misplacement. Whether the others are right or not only extensive experiments will determine. With this rectification, however, they are so far correct that the movements of Nature are opened to us as by a miracle. The lock cleared of this obstruction opens readily to the key, and Materialism rules triumphant. We seem premature; how does the duality of the elements solve all mysteries?

The object of this paper was to prove the materialistic origin of the sexes—that sex had its origin in matter. That matter is dual is part confirmation of it, but, like its antitype, we must also prove dual matter to be productive. Two females will not produce, neither will two males. If a production can be formed from the non-metallic elements only, or metallic only, then our theory is false; production should only ensue from the connection or interaction of opposite sexes and elements. Chemical analysis in this particular shows that we are right. *No natural production can be found containing the elements of only one class;* both metallic and non-metallic are essential to a formation. In simple laboratory experiments the opposite elements will combine readily with one another, while combination cannot be produced among the elements of either class alone. Even the simplest natural productions, such as air and water, are of dual combinations. Air composed of oxygen, nitrogen, carbonic acid gas, *hydrogen*, etc. Water, composed of oxygen and *hydrogen*, is the great medium also of life and production. Even the old *element*, fire or combustion, can only be produced from oxygen and *hydrogen*, with other opposing dual elements. All rock formations, crystals, stratas, are produced from combinations of the dual elements. All plants and vegetation are of dual formation and dual in sex, while all animals are undoubtedly male and female.

Our premises being thus clear and true regarding the elements of the matter, it follows that—as all plants and animals are composed of the same elements, of oxygen, hydrogen, etc., in different proportions and combinations—the conclusion we have been seeking is inevitable, namely, *sex in either animal or vegetable life is derived from and had its origin in the duality of matter.*

What causes dual matter to combine and be productive would lead us into another inquiry as to the origin of life from matter; but this we reserve for future consideration.—*Journal of Science, England.*

THE MECHANICS OF BIRD-FLIGHT.

The mechanics of the flight of birds have been much studied, and considerable space has been recently given to the subject in the columns of the *English Mechanic.* A new contribution has been recently made to a Silesian Society by MM. Legal and Reichel, whose researches deal with the relations of the size of the muscles of flight, and the size and form of a wing-surface, to the power of flight, and a short account may be of interest. (An abstract of the authors' observations appears in a recent number of *Naturforscher.*)

The authors begin by considering the question, whether the absolute size of a bird is of importance with regard to its flying power, *i. e.*, whether two birds, which considerably differ in size from each other, but are geometrically similar in their whole bodily structure, fly equally well. The final answer to this is (as we shall see) a distinct negative. The authors have measured in a great number of birds, the weight of the muscles of flight, especially the most important of these, the great breast muscle, as also its antagonist, the wing raising *musculus subclavius*, and compared it with the body-weight. The ratio of weight of the right and left large breast-muscle to the body-weight varied in the different bird species that were examined, from 1 : 3.4 in the pigeon, to 1 : 10.5 in the gull. But if the bird-species are arranged according to the amount of this quotient, neither the equally good flyers come together, nor birds of equal absolute size; *e. g.*, the partridge stands pretty well forward in the series with 1 : 4.8, near and before the hawk 1 : 5; while the sparrow, stork, and eagle, stand with about 1 : 6 near one another. Certainly, with increasing body-weight, the muscular system concerned in flight does not become relatively greater. The size of the muscles of flight is only one factor in flying-power.

A second, and very important factor is the surface presented by the outspread wing (the wing-surface); and here, again, it is not immaterial in which direction the surface extends. With equal wing-surface, a long narrow surface has more effect than a short and broad one, as a long rudder is more powerful than a short one. The authors have therefore given drawings of the form of the outspread wings for 37 different bird species, and indicated in figures the surface and length (wing configuration). A calculation of the mechanical action showed that where the ratio of the surface and length of the wing to the size of the bird remained the same, the angle of the wing motion and the angular velocity of the wing also remain the same; also that with the absolute size of the bird the air-resistance against the wings increases in the fourth power, but the body-weight only in the third. In order to compare the significance of wing-configuration for flight in large and small birds, one must therefore introduce into the numbers, expressing wing-configuration, a correction according to the absolute size of the bird, and the result of this correction the authors name the wing-number. Now, if the various birds be arranged in series according to wing-number, *i. e.*, according to wing-configuration, with comparative preference of the smaller, the good flyers are found to be at one end of the series, the bad at the other, *e. g.*, partridge 4, wild duck 10, jackdaw 20, sparrow hawk 24, sea-swallow 50. If we now multiply this wing-number with the ratio of the weight of the breast-muscle to the body-weight, *i. e.*, combine the consideration of the actual wing-configuration with that of the relative size of the muscles of flight, which are related to the effectiveness and velocity of wing-beat, we obtain the flight number as measure of the flying power, and this appears, *e. g.*, as follows: Sparrow 0.43, partridge 0.48, wild duck 0.98, jackdaw, 1.72, gull 2.15, kibits 2 92, eagle 2.95, stork 2.97, sea-swallow 3.28.

A comparison of the series thus obtained with the actual flying power, shows that the flight-number in general rises and falls with the flying power and in particular corresponds the better where birds of equal body-size are considered; and less well, the more different the size of the birds compared, so that in larger birds the actual flying power falls behind the comparative flight-number; that even appears, *e. g.*, from a comparison of the partridge with the sparrow. Or conversely, when we compare birds of equal flying power, but different size, *e. g.*, larger and smaller, but adult examples of a species, or species of a genus, the flight-number increases with the body-size. It is indeed difficult and always somewhat erroneous, to measure the actual flying powers of different birds together, one bird accomplishes more in dexterous and quick movements, another in rapid flight in a short time, a third in duration of flight. Still, the result may in general (says the reporter), be regarded as correct. Now, as the flight-numbers express the combined mechanically measurable factors of flight, it follows tha.

with the absolute size of the bird, some flight-hindering element not yet therein contained, increases. We might therefore put the question, whether equally rapid, and (comparatively) equally great contraction in a small bird. In fact, too, it is chiefly the larger birds that present the phenomenon of soaring, a condition in which, the body being maintained at the same height for a certain time, muscular work is saved by special arrangements. If soaring be an advantage, it must, in alternation with periods of active rise by means of rudder-like mechanism, be extensively utilized for the problem of a flying machine.

COLOR RELATIONS OF METALS.

In a paper on the color relations of copper, nickel, cobalt, iron, manganese, and chromium, lately read before the Chemical Society, Mr. T. Bayley records some remarkable relations between solutions of these metals. It appears that iron, cobalt, and copper form a natural color group, for if solutions of their sulphates are mixed together in the proportions of 20 parts of copper, 7 of iron, and 6 of cobalt, the resulting liquid is free from color, but is gray, and partially opaque. It follows from this that a mixture of any two of these elements is complementary to the third, if the above proportions are maintained. Thus a solution of cobalt (pink) is complementary to a mixture of iron and copper (bluish green); a solution of iron (yellow) to a mixture of copper and cobalt (violet); and a solution of copper (blue) to a mixture of iron and cobalt (red). But, as Mr. Bayley shows, a solution of copper is exactly complementary to the red reflection from copper, and a polished plate of this metal, viewed through a solution of copper salt of a certain thickness, is silver-white. As a further consequence, it follows that a mixture of iron (7 parts) and cobalt (6 parts) is identical in color with a plate of copper. The resemblance is so striking that a silver or platinum vessel covered to the proper depth with such a solution is indistinguishable from copper.

There is a curious fact regarding nickel also worthy of attention. This metal forms solutions, which can be exactly simulated by a mixture of iron and copper solutions; but this mixture contains more iron than that which is complementary to cobalt. Nickel solutions are almost complementary to cobalt solutions; but they transmit an excess of very yellow light. Now, the atomic weight of nickel is nearly the mean of the atomic weight of iron and copper; but it is a little lower, that is, nearer to iron. There is thus a perfect analogy between the atomic weights and the color properties in this case. This analogy is even more general, for Mr. Bayley states that in the case of iron, cobalt, and copper, the mean wave length of the light absorbed is proportional to the atomic weight. The specific chromatic power of the metals varies, being least for copper. The specific chromatic power increases with the affinity of the metal for oxygen. Chromium forms three kinds of salts. Pink salts, identical in color with the cobalt salts; blue salts, identical in color with copper salts; and green salts, complementary to the red salts.

Manganese, in like manner, forms more than one kind of salt. The red salts of manganese are identical in color with the cobalt salts, and with the red chromium salts. The salts of chromium and manganese, according to the author, are with difficulty attainable in a state of chromatic purity. He thinks these properties of the metals lead up to some very interesting considerations.

Fire and Water-Proof Paper.—A mixture is made of two-thirds ordinary paper pulp, and one-third asbestos. The whole is then steeped in a solution of common salt and alum, and after being made into paper is coated with an alcoholic solution of shellac.

DETECTION OF STARCH-SUGAR MECHANICALLY MIXED WITH COMMERCIAL CANE-SUGAR.*

By P. Casamajor.

In a previous communication on the same subject,† read before the American Chemical Society at the meeting of March, 1880, I gave several processes for the detection of starch-sugar in commercial sugars. One of these consisted in adding to the suspected sugar a quantity of cold water, somewhat less than its own weight, and stirring the mixture for a few seconds. If starch-sugar is present, it will be seen in the shape of white chalky specks.

Quite lately a sample of yellow refined sugar was given to me which was supposed to be adulterated by being mixed with starch glucose. By applying the test just mentioned, there seemed to be left a few small chalky specks, which dissolved after standing a minute or two, making it very uncertain whether any starch glucose was present. Upon repeatedly trying the same test the result was always doubtful.

I was then lead to treat the suspected sugar by a liquid capable of dissolving sugar, but without any solvent action on starch-glucose. After many trials, I found that methylic alcohol of such density as to mark 50° by Gay-Lussac's alcohometer answered the purpose very well, if previously saturated with starch-sugar, as this solution dissolves cane-sugar, either white or yellow, very readily, but does not dissolve starch-glucose.

Methylic alcohol at 50°, saturated with starch-sugar, gives a solution of specific gravity = 1.25. 100 c.c. of methylic alcohol at 50° dissolves 57 grms. of dry starch-sugar, the volume of the solution being 133 c.c. A solution of starch-sugar in ethylic alcohol does not answer so well, because ethylic alcohol does not dissolve so readily the gummy matters found in soft sugars, which are those generally chosen for adulteration with glucose.

To test the presence of starch-sugar in a commercial cane-sugar, the suspected sugar should, in the first place, be thoroughly dried, as otherwise any water present will weaken the alcohol, and enable it to dissolve more starch-sugar. It should then be stirred for about two minutes with the saturated solution of starch-sugar in methylic alcohol. After this, the residue is allowed to settle, and the clear solution poured off. The residue may then be washed with a fresh quantity of the same solution. After stirring again and allowing the residue to settle, there will remain, if any starch-sugar is present, a certain quantity of chalky white specks, accompanied by a fine deposit, formed by the starch-sugar present in power of fine grains. These finer particles are never seen when water is used for detecting the presence of starch-sugar, as they dissolve in water very readily. It seems probable that by using this solution of starch-sugar in weak methylic alcohol, the starch-sugar in an adulterated sample could be estimated quantitatively by a process somewhat analogous to that of Payen for estimating cane-sugar.

Not having had any occasion for such a process I have not determined experimentally the degree of approximation obtainable in this way.

The methylic solution of starch-sugar should be poured on a filter, after it has dissolved all it can from a commercial sugar, and the residue should be washed out with the same solution, and everything poured on a weighed filter. After all the liquid has run off, the filter and the residue may be rapidly washed with the strongest methylic alcohol fuund in commerce, which tests 92½° by Gay-Lussac's alcohometer, and which dissolves starch-sugar with great difficulty.

By a dexterous use of this process it seems probable that very approximate results may be obtained, although what is said here is merely in the nature of a suggestion to those who may have use for quantitative results.

ASTRONOMY.

THE LATE PARTIAL ECLIPSE OF THE SUN, AND PENNULE'S COMET.

To the Editor of "SCIENCE:"

Though rather late in the day, I send the results of our eclipse observations on the morning of December 30 and 31: I observed the last contact with the diffraction spectroscope attached to the 9½ inch equatorial. The observation was made through the C line, the slit being *tangential* to the limb at the point of contact, and somewhat widely opened. Although the air was very unsteady, and the seeing simply "horrible," yet the instant of the moon's leaving the limb of the sun, as shown by the sudden reappearance of the chromosphere, was well marked. The time was $20^h\ 49^m\ 51^s.0 \pm 0^s.5$, Princeton mean time, or $20^h\ 40^m\ 16^s.5$ Washington mean time.

Mr. McNeill, with a telescope of 3 inches aperture and power of about 40, lost sight of the moon at $20^h\ 49^m\ 36^s$ P. M. T., 15 seconds earlier.

I may mention in this connection that Pennule's comet, as observed here December 18th, 19th and 22d, showed *two* faint tails. One of them was directed, as usual, very nearly opposite to the sun. The other was pointed roughly towards the sun, though deflected some degrees toward the north; the two streamers made an angle of about 150° with each other. Each was about 30′ long on the 18th, and neither was seen after the 22d.

C. A. YOUNG.

PRINCETON, N. J., January 12, 1881.

To the Editor of "SCIENCE:"

Mr. Edwin F. Sawyer has given a very interesting description ("SCIENCE" No. 19, p. 236), of the large bolide of October 25, and the special meteor stream, to which it probably owed its origin, is one which merits prominent notice from the fact that it supplies fireballs of the largest type.

I have collected accounts of no less than 26 bolides, seen during the interval October 26 to November 9, within the last 15 years, which distinctly radiated from this remarkable shower near ε Arietis.

I saw a large meteor belonging to it on Oct. 30, ($9^h 50^m$), 1880. While engaged in telescopic observation I was somewhat startled by two prolonged brilliant flashes, which caused me to turn quickly and I saw at once a very intense meteor streak projected on the sky just S. of α Arietis. It was broken in the middle and endured 25 seconds. Its position was from $38°+18°$ to $26°+22°$.

I received a letter the following day. from Mr. I. Baxendell, F. R. A. S., of Southport, saying he had observed a large meteor on October 29, at $9^h\ 50^m$, with a path from $31°—1\frac{1}{2}°$ to $16°—17°$. The time agreed exactly with that recorded at Bristol, and the two paths gave the radiant at $46°+15°$, which agrees fairly well with that of the notable shower alluded to by Mr. Sawyer.

In further confirmation I may add that on November 1, $10^h\ 50^m$, Mr. H. Corder, of Chelmsford, observed a bright meteor = Jupiter, which had an apparent path from $275°+56°$ to $257°+43°$ and obviously took its departure from the same radiant as that of the fireballs of October 25 and 30.

W. F. DENNING.

ASHLEY DOWN, Bristol, England.

The "Report of the Kew Committee for the year ending October 31, 1880," contains some interesting information connected with an institution which is engaged in a department of research not, as yet, covered by any observatory in this country. The work at Kew is divided into seven sections:—Magnetic observations; Meteorological observations; Solar observations; Experimental in connection with either of the above departments; Verification of instruments; Aid to other Observatories; Miscellaneous.

The Magnetic observations, embracing the automatically registered curves of the Magnetograph, and observations of Declination, Dip, Deflection and Vibration, seem to indicate the approach of a more disturbed period than has occurred for several years. In order to collect more accurate data relating to this subject, arrangements have been made with other magnetic observatories in different parts of the globe to carry on a series of synchronous observations, and the comparison of the results will probably throw some light upon the laws which govern many of these phenomena. In the Meteorological department, self-recording instruments for the continuous registration, respectively, of atmospheric pressure, humidity, wind (direction and velocity) and rain have been maintained in regular operation throughout the year, in addition to standard eye observations made five times daily for the control of the automatic records. Abstracts of the meteorological results are published weekly.

Observations of the sun were made on 246 days, and on only 27 of those days was the sun's surface found to be without spots. A complete copy of the solar drawings made by Schwabe between 1825 and 1867 having been obtained, the Observatory has now in its possession a complete record of the condition of the sun's surface from November, 1825, to the present date. Transit observations of the sun have also been obtained at intervals to correct the local time.

The Experimental department embraces work upon a "Winstaneley's Recording Radiograph," for registering the amount of radiation from the sky, a "Glycerine Barometer," a "Standard Air Thermometer," and various other instruments. A large number of meteorological instruments have been verified and their constants determined for other Observatories and for instrument makers, and facilities for study and experiment have been furnished to a number of individuals interested in the various branches of the institution.

The new observatory which is being erected at Nice under the auspices of the *Bureau des Longitudes*, will probably cost over two million francs. The buildings are partly finished, and Thollon has already done some excellent work there, in spectroscopy. Besides a small equatorial, a meridian circle, and accessory instruments, there is to be a large equatorial of 29.9 in. aperture and 59 ft. focal length, constructed by M. M. Henry, of the Paris Observatory.

W. C. W.

WASHINGTON, D. C., *January* 12, 1881.

THE OBSERVATORIES OF THE UNITED STATES,

I.

CARLETON COLLEGE OBSERVATORY, NORTHFIELD, MINN.

The United States is fortunate in possessing a greater number of well equipped astronomical observatories than any other country in the world. These are distributed over a wide extent of territory, ranging from the shores of the Atlantic to the Pacific coast, and extending from the tropical regions of the Gulf of Mexico, to Lake Superior on the North.

A brief description of some of these Observatories and the appliances at their command may be of interest to our readers, and we propose on this occasion to offer some interesting facts regarding one which has been more recently organized.

The course of instruction in Astronomy at Carleton College, Northfield, Minn., appears to be well organized, and, although the College was fully organized so recently as 1874, it appears to have a well equipped astronomical observatory and every requirement for teaching Astronomy. We are informed by Professor W. W. Payne, in

charge of the Observatory, that the instruments in use are a Clark equitorial telescope, focal length 10½ feet, aperture 8¼ inches; a portable equatorial made by John Byrne, of New York, aperture 4.3 inches; a Howard sideral clock; a Howard mean-time clock, a Bond sideral chronometer, a Fauth transit instrument with telescope of 3 inches aperture, a Clark chronogragh; meteorological apparatus, and a complete set of Johnson's large astronomical maps, recently imported. By courtesy of Lieut. Edw. Maguire, Chief Engineer of the Department of Dakota, the Observatory has also the use of an excellent zenith telescope for special work.

The time of the Observatory is the standard for the State of Minnesota and parts of those States adjoining, and given to the railroad companies daily by telegraph. The distribution of the time of the Northfield meridian by the aid of excellent instruments, is said to be easy, exact and reliable.

The object of erecting this Astronomical Observatory appears to have been three-fold. 1. To give instruction to undergraduate students. 2. To offer opportunities for a complete course of study in Theoretical and Practical Astronomy. 3. To aid in useful investigations.

ON THE LIMIT OF PLANETARY STABILITY.

By Professor Daniel Kirkwood.

Laplace, in his *Système du Monde*, pointed out the limit at which, according to his estimate, the moon's attraction could have retained an elastic atmosphere.* The question of a satellite's stability was also considered by the late Professor Vaughan, of Cincinnati.† I have seen no attempt, however, to obtain for the different members of our system any definite numerical results. In the present paper it is proposed to find the approximate limits of stability in the cases of the eight major planets and certain of the satellites, on the hypothesis that their primitive condition was either liquid or gaseous.

Let M = the mass of the larger or central body,
m = that of the dependent planet or satellite,
x = the distance from the centre of the former to the limit of stability of the latter,
a = the distance between their centres; then, since the disturbing or separating force of the larger upon the smaller mass is the difference between the attraction of the former on the nearest point of the surface of the latter and that on its centre of gravity, we have

$$\frac{M}{x^2} - \frac{M}{a^2} = \frac{m}{(a-x)^2}, \qquad (1)‡$$

or putting $a = 1$ and reducing,

$$x^4 - 2x^3 + \frac{m}{M}x^2 + 2x = 1. \qquad (2)$$

If we adopt the masses and distances given in Newcomb's Popular Astronomy and solve equation (2) for each of the eight principal planets we shall obtain the distance from the centre of each to its limit of stability, as given in the second column of the following table. If, moreover, the planets, with their present masses, be reduced to the sun's mean density their radii as stated in the third column are found by the formula

$$r^n = 430{,}000 \left(\frac{m_n}{M}\right)^{1/3},$$

and the respective ratios of the limits of stability to these radii are seen in column fourth.

* Syst. du Monde, B. IV., Ch. X.

† Pop. Sci. Monthly for Sept. 1878. See also the Proc. of the A. A. A. S. for 1856.

‡ We neglect the centrifugal force due to the planet's rotation, as the modification would be slight and we propose to obtain merely approximate results.

TABLE.

PLANET.	R_n	r_n	$\frac{R_n}{r^n}$
Mercury	165,165 ms	2,514 6 ms	65.7
Venus	701,746	5,719.2	122.7
Earth	1,059,386	6,242.7	169.7
Mars	764,900	2,951.1	259.2
Jupiter	37,354,287	42,335	882.35
Saturn	45,859,381	28,317	1619.48
Uranus	49,512,900	15,209	3255.51
Neptune	81,663,510	16,009	5101.10

On the assumption that in each case the mean density of the separated mass was equal to that of the central body, the sun's present radius multiplied by the respective numbers in column fourth will give the radii of the solar nebula when the planets extended to their respective limits of stability. These radii are less than the mean distances of the planets in the ratio of 1 to 1.265. This fact may have some significance in regard to the former oblateness of the solar nebula or the law of its density.

The Earth and the Moon.—For the moon, which in perigee approaches within 221,500 miles of the earth, the limit of stability is about 38,000 miles. Were the moon's density reduced to that of the earth its radius would be 916 miles, the ratio of which to the limit of stability is 1 : 41.6. The moon's least distance diminished by 38,000 miles is 183,500 miles. If our satellite originally extended to the limit, and if the moon and the earth had the same form and density, the radius of the latter was 165,000 miles.

The Martian System.—The diameter of Phobos, according to Prof. Pickering, is 5.57 miles. If its density, therefore, be equal to that of Mars the limit of stability is about two miles exterior to the surface; or, if the density be to that of the primary in the same ratio as the density of the moon to that of the earth, the limit is less than a mile from the surface of the satellite; and finally if the density were no greater than that of water the satellite, if fluid, would be unstable, the limit being actually within the surface. Since, therefore, the satellite could never have existed at its present distance in a nebular state, it must follow, if any form of the nebular hypothesis is to be accepted, that its original distance was much greater than the present. Can we find a probable cause for this ancient disturbance?

If we suppose the former period of Mars to have been very nearly one-sixth that of Jupiter the close commensurability would render the orbit of Mars more and more eccentric. The planet in perihelion would thus pass through the sun's atmosphere, or rather through the outermost equatorial zone of the solar nebula. This resisting medium would not only accelerate the motion of Mars but also in a much greater degree that of his extremely small satellite. The solar mass contracting more rapidly than the orbit of Mars would finally leave the latter moving in an eccentric path without sensible resistance.

Other Secondary Systems.—For the first satellite of Jupiter the limit is 5250 miles, or 4½ times the radius of the satellite. For Mimas, the innermost satellite of Saturn, it is less than twice the radius. The rings of Saturn, in all probability, could not exist as three satellites, the limits of stability being interior to the surface.*

The effect of preturbation in the dismemberment of comets is known to all astronomers. The nucleus of the great comet of 1880, which approached within less than 100,000 miles of the sun's surface, must have had a den-

* It has been recently shown that Bessel's mass of the ring is much greater than the true value.

sity greater than that of granite, as well as a strong cohesive force between its parts, in order to withstand the tendency to disintegration during its perihelion passage. Had the nuclus been either liquid or gaseous, or even a cluster of solid meteorites, the difference between the sun's attraction on the central and the superficial parts would have pulled the comet asunder, spreading out the fragments into somewhat different orbits, like the meteoric streams of August and November.—*The Analyst.*

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE:"

I have much pleasure in enclosing you a copy of the particulars respecting the formation of our "Field Club," which I believe to be the third in England of similar pretentions, its original founders being Mr. Thomas Kiddie and myself, both being science students, and by profession analysts in manufactories on Coaly Tyne. We were at first inclined to restrict the Club to those of our own class, namely, Students in Chemistry, but knowing the intimate connection between all the other branches of Science and that of Chemistry, we determined to throw it open to all science students, and we are now pleased to find that our efforts have had such a successful issue so far, and met with such general approval throughout the whole district, as we have at present, after two months establishment, about 100 members, some living as far as fourteen miles from our centre; also having the countenance of fourteen gentlemen interested in scientific education as honorary members. The officers consist of students or teachers (under the Science and Art Department, London). Should you consider our club worthy a comment in your excellent journal, which latter must act as a valuable adjunct to the aims of scientific education, I shall be exceedingly obliged if you will forward me a copy to read at one of our excursions.

M. THEODORE DIXON, *Hon. Sec.*

5 BRANDLING PARK, Newcastle-on-Tyne, Eng.

[We print the above letter in the hope that it may suggest the formation of Field Clubs in the United States. The value of such organizations cannot be overrated, and we shall be glad to hear that some of our subscribers have taken the initiative in such an agreeable enterprise. We shall send information to those who desire it.—ED.]

CHEMICAL NOTES.

THE MARQUIS TOMMASSI has succeeded in sending a message across the Atlantic with two Minotto elements.

AN APPLICATION OF ACCIDENTAL IMAGES.—J. Plateau, from some experiments performed by his son, concludes that the *apparent* distance of the full moon is only 50 metres from the observer.

PROPAGATION OF LIGHT.—M. Gouy has shown that there is not, for a given homogeneous source, a determined speed of light independent of the manner in which the amplitude is caused to vary.

PHYLLOXERA IN FRANCE.—It appears that more than a third part of the vines in France have been already destroyed by the phylloxera. The departments of Haute Savoie and Jura are now attacked.

SPONTANEOUS OXIDATION OF MERCURY AND OF METALS.—Mercury, as well as iron, zinc, cadmium, lead, copper, and tin, undergoes on exposure to the air a superficial oxidation, very slight, and restricted by the difficulty of renewing the surfaces and by the want of contact which results from the layer of oxide formed at the outset. For the oxidation to continue this layer must be constantly removed, as in the case with rust of iron formed in moist air, or for each hydrocarbonate produced in distilled water.—M. BERTHELOT.

WINES MIXED WITH GRAPE SUGAR.—The non-fermentable part of the grape sugar which is introduced into wines, if administered to dogs by way of subcutaneous injection produced vomiting and other morbid symptoms. A. Schmitz claims that these residues contain a poison similar to that present in potato-oil.

ACTION OF PHOSPHOROUS UPON HYDRIODIC AND HYDROBROMIC ACIDS.—With hydriodic acid and white phosphorous the latter melts and becomes covered with a reddish layer of biniodide, while phosphonium iodide sublimes. With red phosphorous even at 100°, there is produced merely a small quantity of phosphonium iodide. Upon dissolved hydrobromide acid, phosphorus does not react in the cold. At from 100° to 120°, phosphonium bromide sublimes, but no phosphorous bromide is produced.—A. DAMISEAU.

THE SOCIETE D'ENCOURAGEMENT POUR L'INDUSTRIE NATIONALE has awarded the Le Blanc prize of 1000 francs for the utilization of manufacturing refuse to M. Vincent, for his process for obtaining methyl chloride from the *vinasses* of the beet-root sugar manufacture. A sum of 1000 francs has also been awarded to M. J. A. Martin for his mixtures for rendering textile articles, paper, &c., uninflammable. His ordinary mixture for light goods is: Pure ammonium sulphate, 8 kilos; ammonium carbonate, 2 kilos, (5); boric acid, 3; pure borax, 2; starch 2 (for which may be substituted 0.400 kilo. dextrine, or the same weight of gelatine), and water 100 kilos. A silver medal has been awarded to M. Idrac for his process of drying timber.

A NEW ELECTRIC PROPERTY OF SELENIUM, AND THE EXISTENCE OF TRIBE-ELECTRIC CURRENTS PROPERLY SO-CALLED.—R. Blondlot has observed a new electric property of selenium which may be shown by the following experiment: To one of the poles of a capillary electrometer there is attached, by means of a platinum wire, a fragment of selenium which has been recently heated, and to the other pole a platinum foil. If the selenium is brought in contact with the platinum, holding it by means of an isolating handle, the electrometer remains at zero, as might be expected from the symmetry of the circuit; but if the selenium is rubbed against the surface of the metal the electrometer deviates strongly, the deviation obtained being equal to that produced by a sulphate of copper element.

ANALYSIS OF SUPERPHOSPHATES.—In acting upon a superphosphate made of bone-black or from the phosphate of Caceres with a solution of ammonium citrate of sp. gr. 1·09, there is no occasion to take into account the time of action or the fluctuations in the temperature of the laboratory. In the analyses of a bone-black superphosphate, an excess of citrate must be avoided—20 c.c. are sufficient for 2 grms. of the sample. An excess of the reagent dissolves part of the phosphoric acid of such tricalcic phosphate as has escaped the action of sulphuric acid in the manufacture of the superphosphate. The phosphate of Caceres is much less sensitive to the action of the citrate than the phosphate of bone-black, and here from 20 to 100 c.c. may be taken to 2 grms. of the sample.—L. CHEVRON.

DETERMINATION OF CHICORY IN GROUND COFFEE.—M. Prunier suggests the following method: Two grms. are weighed out and separated from the finer powder by sifting through fine silk. This powder which, as microscopic examination proves, is composed entirely of pure coffee, is set aside. That which remains on the sieve is macerated with a few grms. of water in a test glass. After some hours it is thrown upon a piece of cloth stretched out and crushed with the fingers. The grains of coffee resist the pressure, whilst those of chicory, reduced to a paste by soaking in water, penetrate into the cloth and adhere to it. On drying the cloth it is easy to detach the coffee, which, after dessication at 100° and addition of the fine powder separated at first, gives the weight of pure coffee. The chicory is calculated as loss.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, JANUARY 22, 1881.

Lieutenant Schwatka still remains a prisoner in his quarters on Governor's Island in New York harbor, in consequence of his recent accident. Surrounded by many of the trophies of his arctic experiences, he relieves the monotony of his situation by preparing for the press his forthcoming history of the expedition, with which his name must be forever associated.

Any reference to arctic expeditions at this moment naturally recalls to mind the fact, that a brave American officer and his crew are now locked in the firm embraces of the frozen solitudes of that desolate region, heroically struggling to accomplish a service to humanity.

The gallant De Long may be safe in winter quarters with the Jeannette, waiting for the moment when a channel may be opened for his ship's return; but all past experiences in the polar regions suggest that none but the over-sanguine should rely on such a fortunate conclusion of the voyage, and the common instincts of humanity demand that a relief expedition be immediately organized, to sail at the earliest possible moment to carry succor to De Long and his party, and to report on his condition.

There are other reasons for immediately sending aid to the Jeannette; the attempt to reach the North Pole entails a colossal task, and it is perhaps vain to expect any expedition to reach it by a sudden and unexpected stroke of success; probably nearly four hundred miles of sleigh travelling over rugged and almost impassable hummocks of ice will have to be accomplished at an average speed of six to eight miles a day; this would occupy fifty consecutive days, and then, if all went well, would come the return journey with equal dangers and difficulties. Captain Nares pronounced such travelling impossible.

Lieutenant Schwatka has, however, shown that with better organization and different methods, the dangers of a sleigh expedition can be much reduced. Unfortunately, De Long has not the benefit of "Schwatka's" experiences, and has probably, like "Nares," harnessed his men to the sleigh and not depended upon dogs to drag it over so many tedious miles of dreary wastes. It would, therefore, appear obvious that even should the Jeannette expedition be actually safe and intact, the arrival of new supplies and general aid at the side of DeLong would be most opportune, and may even lead to accomplishing the great object in view.

Possibly some of our readers may consider that the time for sending a relief expedition to the Jeannette has not arrived, and that it may be prudent to await tidings of disaster before help is sent. We have somewhat anticipated such reasoning, but would add that the consequences of such a course in the case of the lost Franklin Expedition led to a final outlay of $10,000,000 by the English nation withnegative results.

We now know that had a relief expedition been sent immediately to the rescue of Franklin, the brave officers and crew might have been easily saved.

Lieutenant Schwatka strongly urges the necessity of sending immediate relief to the Jeannette expedition, and at our request will state in our next issue some of the reasons which lead him to that conclusion. No names have been so far mentioned to take a part in this undertaking, but we trust the services of Lieutenant Schwatka may be secured, as his past experience and great success would give us hope of the best results being accomplished.

The excellent work accomplished by Lieutenant Schwatka, an officer of the United States Army, in arctic explorations, would appear to teach us one lesson, that too great reliance on Naval men reaching the North Pole unaided should not be entertained. Sailors proverbially stick to their ships, are out of their element on shore, and appear unable to cope with difficulties when away from the base of their supplies. Compare the sleigh expeditions of Nares and Schwatka, and note how differently they were managed, the former starting without necessary material, making his men beasts of burden, and failing miserably from the collapse of all his resources.

Schwatka, on the contrary, so contrived that the necessaries of life were always available. Forty dogs merrily drew his sleigh, and with the instincts of a military man he carefully husbanded his resources, and accomplished sufficient to make his expedition a memorable success.

It seems on this account possible that the two arms of the service may profitably combine in the next effort to solve the great Polar problem, for the best results may be anticipated by such united action.

Mr. H. H. Warner, of Rochester, N. Y., offers a prize of $200 in gold for the discovery of any comet during this year. The conditions are that the comet must be unexpected and telescopic, excepting the comet of 1812, and the first discovery must be made in the United States or Canada, and immediate notification telegraphed to Professor Lewis Swift, of Rochester.

THE PHILOSOPHICAL SOCIETY OF WASHINGTON.

At the 191st meeting of the Philosophical Society of Washington, January 8th, the following papers were read: (1). On a Simple Method of deriving some Equations used in the Theory of the Moon and of the Planets, by Mr. W. F. Mc K. Ritter, of the Nautical Almanac office. (2). On the Orbit of Swift's Comet, by Professor Edgar Frisby, U. S. Naval Observatory.

The elements of Swift's Comet were computed by Professor Frisby from three places observed by Professor Eastman with Washington Transit Circle, on the nights of October 25th, November 7th, and November 20th. They werer ecorded in "SCIENCE," January 8, 1881.

From these elements it is readily inferred that it was moving very nearly towards the earth at the time of its discovery (October 10th) by Professor Swift. On November 8th it came very near the earth's orbit, its distance from it being then about 0.069, the mean distance of the earth from the sun. Its perihelion lies a little outside of the earth's orbit, and its aphelion a little outside of Jupiter's orbit. Its perturbations therefore must at some time become immense, but for a long period it will reach its aphelion at times when Jupiter is in a remote part of his orbit. The periodic time from the above elements is about 2178^d, or a little less than six years. Different periodic times have heretofore been deduced for this comet. Some were deduced at 11 years, others at 5½ years, and still others $11 \div 3 = 3\frac{2}{3}$ years. The period of 5½ years is undoubtedly correct, the slight discrepancy being due to insufficient data. At each alternate return to its perihelion it cannot be seen, since the earth is then in the opposite part of its orbit, and the sun is between the earth and the comet. It passed nearest to the earth about the 18th of November.

The logarithms of radii vectores and distances from the earth on the given dates are—

	log. r.	*log.* Δ.
October 25th	0.035328	9.221510
November 7th	0.029018	9.141693
November 20th	0.034557	9.119295

No theory about any periodic time was assumed in these calculations.

THE ROCHESTER MICROSCOPICAL SOCIETY.

At the annual meeting of the Rochester Microscopical Society, held on the 10th instant, the following officers were elected: President, the Rev. Myron Adams; Vice-President, H. F. Atwood; Secretary, H. C. Maine; Treasurer, Dr. C. E. Rider.

This Society now numbers one hundred and nineteen active members, and is stated to be in a flourishing condition. We trust we may occasionally hear from the Society, and that the record presented in our columns may show that a real advance in microscopical studies has been accomplished.

ELECTRIC FISH.*

By the Marchioness Clara Lanza.

The science of electricity and magnetism is clearly acknowledged to be an acquisition belonging to modern times, we might say to the last century. To the ancients this great world of ideas was completely unknown, with the exception of a few individual facts which must have appeared to them in a very puzzling light, as philosophy and physics were in a wholly powerless and perplexed condition.

If we pass over the electric phenomena of our own atmosphere, thunder and lightning, the only facts concerning electricity known to the ancients were the capacity of the magnet to attract iron, the attractive power arising between two pieces of amber when rubbed together, and the peculiar effects exhibited by electric fish.

One of the most numerous and common fish found in the Mediterranean Sea is the torpedo, which is able to eject electric shocks of such force that a man's arm has often been lamed by them. The knowledge of this fact can be traced back to the farthest antiquity. These fish are so often seen on the coasts of Italy and Greece that the effects produced by them must have led to the first experiments, made, in all probability, by fishermen and people directly inhabiting the coasts of these countries; at all events, the knowledge of this fact is much older than that relating to the magnet and amber, which certainly extends to a remote pre-historic period.

The Greek designation of these words, magnet and amber, contains no etymological relations to the qualities peculiar to these bodies, which must have appeared so mysterious to the ancients. The Greek term for magnet, *Heraklea* and *Magnetis*, denotes simply a stone found in the City of Heraklea or Magnesia—while the Greek word for amber, *Electron*, relates merely to the color of the substance. In this way it is evident that both the magnet and amber were long known to the Greeks and named by them before their peculiar physical properties were ascertained.

With the torpedo it is different. The ancient Greeks called it *Marhe*, and the verb derived from this substantive signifies to stun. In the same way the Latin name, *Torpedo*, denotes something which produces numbness and lameness. In the fish markets of Marseilles and Toulon, the torpedo is called *torpille*, and thus the word torpeur, (derived from the Latin *torpor*), is used in French to denote numbness and stupefaction. The Italian fishermen call it *Tremola* on account of the characteristic trembling sensation which its touch produces. In the Arabic *patois* of the Maltese, *Haddaila* is the name applied to an electric fish.[1] Thus we find that everywhere the name of the torpedo is etymologically allied to its electric capacity, which makes it evident that the knowledge of its peculiarities extends to the most distant period in the construction of language.

Perhaps of no more recent date is the practical and most interesting use which the inhabitants of the Mediterranean countries made of the torpedo's electric capacity, thus undoubtedly representing the beginning of electro-therapeutics. As a certain cure for headache one or more living torpedos placed upon the affected part was strongly recommended—just as at the present time a constant galvanic current is used as the most reliable manner of curing the same complaint.

Aside from this, the numerous passages in the Greek and Roman authors which relate to the torpedo and its effects are mostly of a subordinate interest. Their language, like ours, struggles to express that numb and trembling sensation occasioned by the electricity proceeding from the fish, and which we ourselves are unable to describe and simply designate by the name of "electric

* Translated for "SCIENCE" from the German of Prof. Franz Boll.

1 John Davey, *Anatomical and Physiological Researches*. London, 1839. Vol. I.

shock." We are informed that the fish makes use of this power to defend itself against its enemies, and also as an offensive weapon towards its victims. This means of defense, however, does not only take effect in consequence of immediate contact, but likewise when the fish is quite removed from all association with any object. It is well known that the shock has been clearly felt, as if by close contact, (harpoons, etc.), by fishermen who drew towards land a net in which was found a torpedo. When a stream of water was poured from a vessel upon the fish, the men's hands were powerfully affected, just as the frightful, stunning sensation is conveyed to the unsuspecting angler through the medium of his fishing line.

It is greatly to be regretted that the most celebrated natural investigator of antiquity did not turn his attention to torpedoes. Among the writings which are attributed to Aristotle only very brief mention is made of this extraordinary creature. This is the more to be wondered at inasmuch as Aristotle speaks of the torpedo in reference to something else, and appears to have a complete knowledge of its anatomy. He, therefore, knew that it belongs to a viviparous species, a fact which, in our own time, has been disputed by Cuvier.

Aristotle having failed to give any explanation of the torpedo, it is, perhaps, not astonishing that the rest of antiquity did not enter upon the subject. Indeed, among all the writings of the ancients which treat of the torpedo, there cannot be discovered the slightest attempt to throw any light upon this wonderful phenomenon and reduce it to purely natural causes. The best and most intellectual article found among ancient writings in regard to this point is from the pen of the Greek physician, Galenus, who lived in Rome about 200 years after Christ. He compares the effects of the torpedo to the working of the magnet.[2]

Besides the torpedo there is another electric fish belonging to the realm of antiquity, and in exact opposition to the former, a fresh water fish. In reality, in all the rivers of Africa, especially the Nile and its neighboring streams, from mouth to source, one of the most common fish to be met with is the ***Malopternus electricus***, the electric Silurus. In size and electric power this fish is almost equal to the torpedo, but in other respects it is totally unlike the wonderful salt water creature. It is exceedingly interesting to observe that in this fish the same etymological relations and the same remedial representations in regard to nervous maladies, are found as in the torpedo. Unfortunately we are not acquainted with the name applied to it by the old Egyptians, nevertheless, we know that from the invasion of 638, which laid the foundation of the Arabian language and culture to the present day, the fish has been called ***raâdah*** or electric fish. The Jesuit Godigno, who in the sixteenth century undertook a journey to Abyssinia, tells us that the Ethiopians made use of this fish for the purpose of "casting out devils," or in other words to cure nervous diseases.

A passage in Athenæus where the ***Marhe*** is represented among the Nile fish proves that the Greeks were aware that electric fish were found there. Yet, the electric Nile fish appears to have been unintentionally identified by them with the Mediterranean torpedo, as mistakes and misconceptions concerning them extend far into the past century.

Abd-Allatif, a physician of Bagdad who lived in the twelfth century, writes as follows in his history of Egypt: "Among the animals peculiar to Egypt, we should not forget the fish called ***raâdah*** for the simple reason that while it lives no one can touch it without experiencing an irresistible trembling sensation. This impression is accompanied by cold, numbness, a crawling feeling and lameness in the limbs, so that it is impossible for one to remain in an upright position or hold anything. This extraordinary stupefaction extends through the arm, the shoulder and entire side, however superficial and light the contact with the fish may have been. A fisherman assured me that when such a fish is caught in a net, the effect produced is distinctly felt by the man, although his hand does not touch the fish, and even remains some distance from it. When dead the *raâdah* loses this power. People accustomed to bathe in water where this fish is found say that the mere breath (?) of the *raâdah* is sufficient to produce such numbness of the body that the person affected can scarcely keep from sinking." [3]

We see that the knowledge of Arabian physicians concerning the Malopternus amounts to about the same thing as that obtained by the Greek and Roman authors in regard to the torpedo, and in both cases we are unable to discover the slightest trace of any inclination to analyse the mysterious effects of the fish.

Four hundred years later than the celebrated Arabian physician, the Jesuit Godigno, journeyed on the Nile. He speaks of the electric silurus in exactly the same terms as his predecessors, and it would be useless to mention it here in any special way, if his travels did not refer for the first time to a fact, which as an unconscious example in the study of animal electricity, deserves a place in the history of science. Godigno says:

"The Ethiopians assert (I myself have never witnessed the fact) that if a living electric fish is placed upon a heap of dead fish and allowed to move among them, the fish thus brought in contact with it are seized with an inward and inexplicable trembling to such an extent that they actually appear to be alive. The cause," he continues, "may be authenticated by those who investigate the nature of things in general, and I leave it to them to decide as to what this force of motion communicated by the electric fish to the dead ones may be."

The next author upon this theme, Francesco Redi, distinguished alike as physician, natural investigator and poet, gloriously opens the path for earnest and systematic research.

The beginning of this new era in the history of electric fish can be ascertained even to the day and hour. On the 14th of March, 1666, a freshly caught torpedo was brought to Redi, and to the examination and dissection of this one specimen we owe his masterly physiological and anatomical description of the torpedo, which no anatomist can read without the utmost admiration, and which casts the collected wisdom of antiquity into complete shade.

The most important advancement attributed to Redi, is the discovery of peculiar symmetrical organs situated on each side of the torpedo's head. To-day they go by the name of "electric organs," although the discoverer called them falciform muscles or bodies, and they were known to anatomists as such for more than a century. "It seemed to me," said Redi, in relating his experiments, "as if the painful sensations caused by the torpedo had their origin in these two falciform muscles more than in any other place." Thus the first hints were given towards the correct understanding of the fish, and the inexplicable strength of its electric power pointed out together with its peculiar organs.

Redi's suppositions were soon proved to a certainty by Lorenzini, one of his pupils, who in the year 1678 published an anatomy of the torpedo. From that period until the present day, the study of electric fish has always taken the anatomy, physiology and physics of the falciform organs for its subject, and by this means has been able to obtain deeper and more extensive knowledge. Now the torpedo is no very mysterious object, but at the same time the following question remains more or less open to discussion: How is this wonderful electric organ made, and how is the creature able to produce such extraordinary effects by means of it?

2 *Galeni opera ed. Kuehn.*—Vol. VIII., p. 421.

3 Relation d'Egypte, par Abd-Allatif, médecin Arabe de Bagdad. Traduction de M. Silvestre de Sacy, Paris, 1810.

The first attempts at solution given in regard to this inquiry were of a singularly mistaken character. It has already been said that Redi designated the electric organs as falciform muscles or bodies. This unintentional comparison of the electric organs with muscles has played an important, though by no means wholesome, part in the history of electric fish.

With that broad comprehension, that massive reproduction which subordinate intellects often accord to the master's ideas, Redi's direct successor and pupil, Lorenzini, plainly indicated the electric organs as "falciform muscles," thus entirely overlooking his teacher's apt precaution on this point. And from Lorenzini every anatomist of the following century calls these organs distinctly, and unalterably muscles, although this appellation is completely voluntary, and notwithstanding the fact that the electric organs, outwardly as well as inwardly, are totally unlike muscles of any kind.

If these organs, however, *were* muscles, it was but natural that effects analogous with those produced by muscles should be ascribed to them. There followed, consequently, a purely mechanical theory respecting the action of the organs, which was best set forth by Borelli, in 1685. His opinion was that they contracted several times in quick succession, thus giving a number of violent repulsions to the object brought in contact. This, he thought, was followed by a cramp or spasm of the same nature as that experienced by a person who strikes his elbow sharply. This theory met with universal applause. The most prominent natural investigators, Linné, Réaumur and Hallere agreed perfectly with Borelli, and we may say that until the year 1750 the idea was recognized everywhere as the only possible and complete explanation ever given.

From the time of Redi to Réaumur the investigators limited their experiments to the electric fish most accessible to them—the torpedo. The electric silurus of Africa is scarcely mentioned, and if spoken of at all, it is merely to mistake it for, or identify it with, the torpedo. However, during this period the third and last known electric fish was discovered—the electric eel (*gymnotus electricus*)—found in South American rivers, and possessing the greatest bodily dimensions and the most powerful electric properties of any.

The first news of the gymnotus reached Europe about the year 1672. Later, Alexander von Humboldt made the fish famous, by describing in his book of travels, its fierce struggles with horses. Humboldt tells us that the name "Arimua," given to the eel by the South American Indians, denotes a creature that deprives of motion. He also states that in former times the gymnotus was used as a cure for paralysis. We may judge of the tremendous violence of the eel's electric discharges by quoting a fact related by Humboldt.

"On one occasion the inhabitants of a certain town were obliged to turn a street in an opposite direction because the electric eels had increased to such an extent in the rivers that every year they killed quantities of mules which were accustomed to wade through the water heavily laden."

However, before more complete information concerning the gymnotus could reach Europe, the youthful study of electricity had undergone an important modification which was destined to bear direct influence upon the theory regarding electric fish. The discovery of the Leyden jar (1745), spread through the world, and attracted universal attention. Experiments were made in all parts of the country, and everyone was anxious to learn the effects of this new natural force by his own experience and sensations.

Under these circumstances, it is not surprising that Adamson, who had studied the effects of the Leyden jar in Paris, on becoming acquainted with the electric eel in Senegal (1751), compared the latter with the former, and remarked that the shocks could be communicated like electricity through an iron wire. Dutch investigators state the same thing in regard to the gymnotus. Its electric shocks can be conducted through a chain composed of several persons, but it is maintained that only the electric conductors transmit the shock, while insulators can touch the fish without any effect being perceived.

Nevertheless, serious doubts arose concerning the correctness of this new theory, until the year 1772, when John Walsh, an Englishman, irrefragably demonstrated the electric nature of the torpedo in a series of experiments given at La Rochelle, the old Huguenot town, in the house of Marie Seignette, the discoverer of Seignette salt. He showed simultaneously that the moment the shock occurs the back and stomach of the torpedo are differently situated in regard to the electricity. Walsh considers the "falciform muscles" as mere electric machines that are put in motion at the will of the animal. Soon afterward this old term disappeared from science altogether, and the more appropriate appellation of electric organs was bestowed in its stead. A few years later, this same Walsh undertook to make a series of experiments upon the gymnotus, several living specimens having been brought to London at his request. The conformity of the shocks was perfectly demonstrated by an electric discharge; indeed, Walsh even succeeded in causing the gymnotus to emit distinct electric sparks. Cotemporary with these experiments by Walsh, the correctness of his theory was demonstrated in another interesting manner. The eminent natural philosopher, Cavendish, sunk under water a wooden board covered on each side with tin foil, and succeeded in imitating the electric phenomena of the torpedo as demonstrated by Walsh, by simply connecting the two sides of the board with a Leyden battery. He thus showed the curved current of the water, which completely agreed with that produced by the electricity of the torpedo. Finally he demonstrated the fact that a hand thrust into the water, although not coming in contact with the fish, must yet be affected by the electric shock proceeding from it in proportion to the distance.

Investigators received a fresh impulse through the discovery of galvanic electricity and electro-magnetism. It remained to be shown, however, that the electricity produced by the fish really possessed all the distinguishing features of galvanic electricity. Alexander Bolta planned numerous experiments, which, unfortunately, were never put into execution. At the instigation of the celebrated chemist, Sir Humphrey Davy, however, one of his brothers, John Davy, performed extensive experiments in Malta upon the torpedo. He observed the diversion of the multiplicator, the magnetizing of a steel rod, visible sparks, decomposition of water and nitric acid, the reduction of iodine from iodide of potassium, and, in short, the complete register from a galvanic current to the production of physical effects. He also maintained, in regard to the direction of the galvanic current, as observed in the torpedo, that at the time of the shock the creature's back is positively situated the same as the stomach. It is to the efforts made by the first natural philosophers, Faraday, Schoenbein, Colladon, E. du Bois-Reymond, and others, that science owes the explanations given in regard to the two other electric fish, the gymnotus and the silurus. It has been ascertained that the current in the former flows from head to tail, while in the latter it takes an exactly opposite direction.

Anatomists were no less prompt by exploring the construction of the electric organs than natural philosophers were the physics. The most distinguished names in anatomical science consecrated themselves, so to speak, to this particular theme. An account of these investigations can be read in the works of John Hunter, Etienne Geoffroy, St. Hilaire, Pacini, and Max Schultze. The descriptions of the torpedo and silurus written by Paolo Savi and Th. Bilhary are masterpieces of anatomical research. Unfortunately, we are still without a like description of the gymnotus.

In order to obtain a thorough comprehension of the electric organs and their action, it is necessary to have re-

course to a third science, experimental physiology, to unite anatomy with natural philosophy, and thus make the result of one answer for the other. Whoever wishes to acquire a clear idea of the three electric fish and their organs must moreover keep the following points always uppermost in his mind:

The electric fish already mentioned as representing three different species are by no means individual fish as may, perhaps, be supposed. On the contrary, they are in form very similar to those belonging to the same families. For instance, the electric eel resembles, to an extreme degree, the common eel, the electric silurus those of its species inhabiting our rivers and lakes, and the torpedo all others of the ray family. Ancient zoology associated the electric fish with others of its kind which possessed no electric capacity whatever.

In each of these fish the electric organ is constructed in a unique and highly interesting manner. The most simple of all is that of the torpedo. This creature possesses two electric organs, symmetrically placed, one on each side. Like all fish of the ray species it is distinguished by a flat, broad body. However, while the ray usually has a somewhat pointed head, the torpedo has a remarkably wide one. This arises from the fact that in addition to the gills on each side of the head, the falciform electric organs discovered by Redi are also situated there. They extend along the body, one directly under the skin of the back, the other beneath the skin of the stomach. The dimensions of these organs is especially worthy of attention. In a torpedo of ordinary size (35 centimetres in length) the electric organ is about 11 centimetres long, the greatest width 5 centimetres, and the height, (the skin being removed from the back and stomach), 2 centimetres. When prepared, the organ is of the consistency and not unlike a gray, semi-transparent gelatinous substance.

In the electric silurus, as in the torpedo, a symmetrically placed organ is found on each side. It lies on the skin which assumes the thickness of a tough rind. With the exception of the extremities, (the tip of the head and tail), the substance of these organs is embedded in the entire skin of the fish. In the middle line of the back and stomach the two organs come in direct contact, so that we may say the body of the silurus is placed in a tube composed of the two electric organs which unite like two gutter tiles. From the ends of this tube the head and tail of the fish alone project, as the skin covering them contains no electric substance. When in a fresh condition the material composing the organs presents very much the same appearance as that of the torpedo. The size is considerable, the weight being more than one-fourth that of the entire body.

The electric organs of the gymnotus are by far the most extensive. This creature, the largest specimen of whose species measures the length of a man and the thickness of a good-sized thigh, does not possess the same strongly-developed, muscular constitution which distinguishes our common eel. Almost the whole body from the back of the head to the end of the tail is composed of electric organs which are situated along the vertebral column in two pairs, a large one above and a small one beneath. Above these organs, and aside from the vertebral column, are the muscles (reduced to very insignificant dimensions) which move the powerful body.

This, then, is the way in which the electric organs are distributed among the three fish, without causing them to differ in any other respect from the remainder of their species. Yet we must make one limited addition to this assertion.

The electric organs are all distinguished by an extraordinary abundance of nerves. To each individual organ is attached an immense number of nerve-fibres, which complete it in some remarkable way yet to be spoken of, and which must be regarded as a constituent part of the organ itself.

It is, of course, understood that these nerve-fibres (called electric nerves) are entirely wanting in the organization of the non-electric fish, and nothing analagous with them can be found in the latter's entire construction.

But we must go a step further. It is a fixed law, governing the entire vertebrate world, that every nerve shall spring from a particular point, or rather from a certain group of cells belonging to the organs of the nerve centres (brain and spinal cord). This group is called the centre of origin of these nerves. In many cases the individual nerve-fibres have been successfully traced to the separate ganglion groups (nerve cell groups) of a like number of cells. In these cells single apophyses have been well authenticated and make it evident that the latter become nerve-fibres in course of time; or rather the nerve fibres have been carefully observed as to their position in regard to the centre of origin, and thus warrant the conclusion that they unite with the apophyses of the ganglion cells.

In the torpedo the powerful electric nerves (five on each side) unite with the centre organ between the brain and spinal column, and form their centre of origin on each side in a massive lobe first described by Alexander von Humboldt, and called the lemon lobe on account of its peculiar color. Now the name has been changed to electric lobe.

A close microscopic examination has shown that this consists entirely of ganglion cells and nerve fibres. These excited special interest for some time among anatomists, as it was discovered that their dimensions much surpassed those of all other nerve fibres and ganglion cells.

Then Bilhary disclosed the fact that in the electric silurus, the numberless nerves which support the electric organ originate from the subdivision of a single collossal nerve; also that this enormous fibre springs from an equally large ganglion cell visible to the naked eye, which lies imbedded in a substance of its own not far from the upper end of the spinal column, and forms the electric centre of origin of the fish.

The nerves which constitute the electric organ of the gymnotus are unusually great in number (200—230 on each side). They are situated along the entire length of the spinal column and at each interval between two dorsal vertebra a nerve projects. Their origin has not yet been explained in a satisfactory manner, but the most probable supposition is that they spring from certain large ganglion cells which are found along the spinal column.

The above details show us that the three electric fish possess specific electric organs and electric nerves, and that the construction and situation of the central organs differs exceedingly from that of the nerves. If a closer examination is made, it will be seen that the three electric organs harmonize perfectly with the essential parts of their structure, and that an anatomical principle binds them together.

This anatomical principle is nothing more than the construction of the electric organs out of many thousands of perfect, symmetrically arranged layers, the so-called electric strata in which the nerves terminate. Apart from these layers there is no other demonstrable formula of the electric organs except blood vessels and tissues.

In the electric organ of the torpedo which lies between the paralleled flat portions of the back and stomach, the electric layers are arranged in a corresponding manner. They are distinguished by having a rough and a smooth side. The latter is turned towards the back, the former towards the stomach. The rough side is so called from the countless nerve ramifications which spread themselves on all sides, and at last become so diminutive that they appear to melt into the electric layers composed of a pithy, albumen-like substance. It is very much to the point that these thousands of layers should be identified as a summary of electro-motory units, and that the construction of each individual layer should be investigated in order to discover, if possible, the reason for the phen-

omenon. The fact that the nerves of the layers turn towards the negative flat portions of the fish when the shock takes place, appeared to give a by no means unimportant hint, and to indicate a relation existing between the disposition of the nerves and that of the shock.

With the gymnotus all the different proportions harmonize completely with each other. The electric layers are situated vertically along the body. A rough and a smooth side are quite distinct. In the latter numberless nerves are embedded. The rough side corresponds to the tail and the smooth side to the head. The same relations exist here as in the torpedo. With the gymnotus, however, the current goes from head to tail, and when the electric shock takes place, the nerves of the strata turn towards the negative pole of the fish.

This harmony between the nerves and the electric shock leads us to suppose that an effectual and universally recognized law is in question. Yet, while the whole world was expecting a like agreement in regard to the malopternus, anatomical and physical investigations of its organs showed a considerable difference existing between them and the two first described. It is true that electric layers are there, and also situated vertically along the creature's body. The nerves too, unite in the same manner and on the same side with the layers. But a rough and a smooth side cannot be distinguished here as in the torpedo and gymnotus, for the layers are not furnished with so great a number of nerve fibres. On the contrary, one single nerve fibre is implanted in the centre and corresponds with the tail of the fish, as is the case of the gymnotus. When the shock takes place, however, this is the positive and *not* the negative pole.

So far, no one has succeeded in removing this contradiction, and it is more than questionable whether the resemblance agreed upon by Pacini between the anatomical and physical relations of the electric layers, has really the value of a natural law or not. In laying down this principle an important anatomical fact is first to be considered which later years have succeeded in ascertaining. It has been said that the electric layers in the gymnotus possess an identical microscopical structure, which formerly was only known in the torpedo and silurus. Unfortunately, the gymnotus has not been successfully examined in regard to this, therefore the question concerning the physical explanation of the electric shock has not much significance.

These are the facts which Anatomy is capable of producing in regard to the structure of the electric organs, especially in all that concerns their relations with the nervous system. No less great is the number of facts ascertained by the means of experimental physiology, which first facilitated a thorough understanding of the electric organs and their import.

Before these facts are individualized, however, it is necessary to make a few general remarks concerning the physiology of the nervous system.

All the organs contained in the body with which those springing from the centre of origin of the nervous system unite, can be divided into two classes, according to the relation they bear to the nervous system.

First class: Organs with centripetal nerves (commonly called organs of sense). These are characterized by the fact that any influence directed upon them through the nerves is conducted to the organs of the nervous system, and there produces a sensation. This perception arises from the peculiar nature of the nerve in question. If the retina of the eye is attracted by anything, a sensation of light is produced, which influences the nerves of the skin. Any excitation of the organs of hearing causes a resounding sensation upon the nerves. Indeed, it is not even necessary that the corresponding organ should be directly attached at all. The same effect is produced when the nerve of the organ is cut and any excitation made upon the end which does not unite with the central organ. If the influence is directed upon the periphery end of the divided nerve which is attached to the organ of sense, no natural effect will be perceived.

Second class: Terminal organs with centrifugal nerves. These do not include the organs of sense, according to any general signification. The muscles, the organs of sight, and probably the glands, all belong here. These organs, differing so completely one from the other, bear the same general relations towards the nervous system. Every influence which effects the centre of origin, particularly one made at will by the animal in question, is conducted through the nerves of the final organ, and, according to the nature of the latter, produces muscular contraction. Here also it is unnecessary that the excitation should proceed directly from the centre of origin. The same effects appear when the nerve of the terminal organ is cut and any influence directed upon it. If the excitation be directed upon the end of the nerve in connection with the centre of origin, there is no result.

It is to the second class that the electric organs belong. They are under the direct influence of the nervous system just as other organs are. They are distinguished merely by their peculiar properties, and they develop under the controlling power of the nervous system just as the muscles contract and expand by the same means.

The proof of this analogy has been given in a most complete manner by Physiology, and we will repeat it here, or, rather, give the principal details.

If the centre of origin of a muscle or any group of muscles is excited in an animal, contraction takes place. A needle thrust into the electric strata of a living torpedo occasions an immediate electric discharge.

The same results are observed when the excitation is made upon the end of the nerve connected with a muscle instead of the centre of origin.

If an electric excitation is selected for this experiment it will be seen that every irritation, however superficial, made upon the nerve proceeding from the muscle is followed by an electric shock.

If the irritations follow each other in quick succession the convulsions will be reduced to an apparently invariable state of contraction which Physiology designates as tetanus. The same excitations directed upon the electric organ produce the same effects. This is called electric tetanus.

It has been observed that a short space of time ($\frac{1}{100}''$) elapses between the nerve excitation and the beginning of the convulsion during which the muscle remains perfectly motionless. When the nerve of the electric organ is irritated the same result occurs.

The muscles and electric organs of animals which have been poisoned by strychnine produce very interesting effects. The nature of this poison consists (as physiology expresses it), in a condition of complete reflex irritability, that is, a state in which every excitation experienced by the nerves of sense is answered by some modification of the centrifugal nerves. If, for instance, we take a rabbit or frog which is poisoned by strychnine and shake it violently or scream loudly, you will see that spasmodic muscular contraction follows each successive irritation. If an electric fish is poisoned by strychnine the same contractions are produced, followed by an electric discharge.

We must not forget to mention that the electric organs as well as the muscles are liable to fatigue, and that just as the latter lose their capacity for contraction after continuous labor, so are the former incapable of producing any effect after repeated discharges have taken place.

The immense number of concordant facts which can be proved in regard to the electric organs and muscles, has induced physiologists to assume that an especial anatomical and physiological relation exists between them, and many consider the electric organs to be muscles remodelled in some peculiar way in which the development of electricity instead of force, and the electric shock instead of contraction, had taken place by some inexplicable means. Such suppositions as these stand in direct

opposition to physiological, chemical and anatomical facts, which recognize a vast difference between these two organs.

The preference certainly is due to that mode of investigation which casts away all artificial proofs of closer relationship between the muscles and the electric organs and regards them as independent and well-authorized members. Indeed, the reasons given by those who accept an especial connection between the two are formed merely upon the identity of this relationship with the nervous system, and not upon any similarity to the actual qualities peculiar to these organs. Such grounds, however, can have no importance as regards this question and can bring the electric organs no nearer to the muscles than to the organs of sight or any other organ.

But are the electric organs really so independent and isolated in the animal organization? And to what freak of nature are we indebted for the remarkable fact that out of all the fish that exist, only three are distinguished by such powerful weapons? The theory of evolution which now rules organic natural sciences, always has a well-tried domestic remedy on hand for such questions. This theory discovers in formations like the electric organs which stand out as prominent exceptions to the conformity of animal construction, the distinct remains of a powerfully developed species belonging to an early epoch of geology, or, in other words, the solitary descendants of a once mighty family. According to this, the appearance of the electric organs in the three fish may seem much less mysterious, and the great anatomical diversities which exhibit themselves throughout these organs are, perhaps, best explained by the idea that in these fish we have before us the final issue of a powerful species, the last remains of an extinct family. That such a family did exist is proved by the discovery of a petrified torpedo in the tertiary strata of Monte Bolca in Verona.

But also in the cotemporary creation the electric organs are not so badly devoloped as a superficial observer might suppose. In the non-electric torpedo of the *Kaja* species, and also those which are found in the African rivers, peculiarly constructed organs have been discovered from which an electric effect cannot be produced, but which, nevertheless, are composed of strata similar to the real electric organs. These may, perhaps, be correctly termed electric organs, which are either newly constructed or else in a state of incomplete development.

The materials so far collected by anatomists and physiologists concerning this question do not admit of a marked decision. The organs present many things in common with the electric strata it is true, but beyond this further investigation seems useless.

In one other respect physiology is likewise unable to give a definite explanation. E. du Bois-Reymond was the first to ask how it happened that the electric fish was not the victim of its own power, and how it was possible that the forcible electric discharges which killed other fish completely escaped the electric fish itself.

Now we all know that the nerves and muscles of the electric fish are excited by means of an electric current, and a much stronger one is perhaps required here than would be the case with other animals, yet the electric discharges, although of such force, produce no effect whatever upon the fish. There are influences at work here, which so far we are unable to understand. We naturally suppose, however, that the great dimensions of the nerve fibres and ganglion cells, together with a vigorous nervous system, have a great deal to do with it.

In conclusion, it still remains for us to put the greatest question of all concerning the electric fish, namely: what is the origin of that powerful force which at the creature's will so suddenly appears and departs with equal rapidity, and also what is the precise mechanism of the electric organs?

It has been shown that as science advanced, the electric fish became better known and more carefully studied. The ancients were only aware that such a thing existed; a conviction, however, that they were incapable of analysing further. Redi taught us to consider the electric organs as the apparatus which produced the effect. E. du Bois-Reymond put the electric strata in place of the electric organs, by proving that the mechanism of the latter was reduced to the combined action of countless analogous electro-motory monads, which was explained by the supposition that when the electric discharge occurred one part of the strata was positive and the other negative. By this means our question concerning the mechanism of the electric organs is partially answered. It now remains to ask what takes place when the electric discharge occurs?

Now, in order to imitate the effects produced by the malopternus, it requires the strongest electro-motor apparatus that can be found. The natural philosopher must use the most powerful batteries contained in his labratory, if he wishes to *approach* the force which causes 2½ pounds of water, salt and albumen to come under its influence.

The muscles are no less powerful. The dorsal muscle of a frog consists of a few grammes of water, salt and albumen, and yet it is capable of lifting a kilometre. In both cases an extraordinary development is apparent, mechanical in one and electric in the other.

Hitherto, no one has succeeded in correctly establishing the facts relating to this mechanism. Nevertheless, concerning the electric eel there is an accepted theory, which explains all the phenomena in a most satisfactory manner.

This theory originated with Colladon and E. du Bois-Reymond, and states that in the electric substance, dispolary electro-moter molecules are to be found.

In a state of repose they turn towards their pole in every direction, or else in two ways opposed to each other, so that the electricity arises on all sides and disappears without. When the shock takes place, the possitive pole is turned quickly towards the electric organ whence the positive current proceeds.

OBSERVATIONS ON ICE AND ICEBERGS IN THE POLAR REGIONS.*

By Lieutenant F. SCHWATKA, U. S. N.

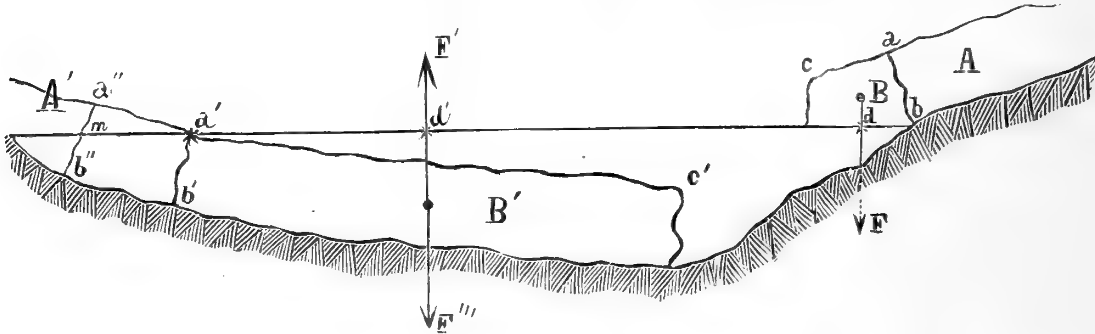
The formation of icebergs, from the terminal fronts of glaciers, has long been a disputed point among *savants*, some contending that they derive their origin from the corroding action of the water, undermining their projecting faces until the weight of the superincumbent mass, acting as a lever, overcame the cohesive power of the glacier along some line of least resistance, when the berg fell into the sea, and was wafted away by the tide-winds and currents. Others can only account for such huge mountains of ice by supposing that the glacier, slowly crawling into the sea, and plunging beneath a denser fluid, has a bouyant effort or tendency to rise, which, at last, becomes so great that it overcomes the line of least resistance, near the shore, and the berg rises into the sea, to be at the further mercy of its uncertain elements. Both theories have proved to be correct. The former generally occurs where currents, heated in more temperate climes, pour their tepid waters northward, and expend their thermal forces in contending with the vast packs, floes, and glaciers of ice, that obstruct their polar march, and whose fast corroding action has the slow glacier only a comparatively short time in its embraces before it has undermined it. The latter results where the chilled waters from the Pole have but little effect upon the glacial front; and slow as it is, it has time to crawl into the sea to give forth its mighty masses. Sometimes both

* Read before the National Academy of Sciences, New York, 1880.

kinds of forces are acting simultaneously upon the same glacier, and while huge icy mountains are at intervals of centuries rising from their dense, watery bed, other and smaller ones are more frequently dropping from its seaward face, for those formed by dropping are far smaller than those which rise into the sea, as the following diagram will serve to show. Although about seven-eighths of an iceberg is submerged, it must not be inferred that, when its height has been determined, seven times that height is its depth below the sea level. If of a tabular shape, this proportion becomes more nearly correct; but if of a pyramidal or conoidal cross section, which is far oftener the case, the lineal proportions of height to depth approach each other more closely, while the volumes, necessary to hydrostatic equilibrium, remain invariable. Their great height, as compared with their breadth shows that these lineal proportions do not obtain beneath the sea level,or the mass,if homogeneous could not be in a state of stable equilibrium, and would topple over, which sometimes happens when the conditions of equilibrium are disturbed by the unsymetrical decrease of its different faces.

The height of bergs, estimated or measured by various Arctic voyagers, varies greatly. During the warm months of summer, when they are most frequently encountered by navigators, they are often surrounded by a hazy mist, due to the condensation of the surrounding moisture by their chilly faces, and the effect is to make them appear much higher than they really are, and to render estimates of their height particularly unreliable.

As about seven-eighths of an iceberg is under water, the curious spectacle, which has often been seen in Polar latitudes, of these monsters ploughing their way against a rapid current, loaded with heavy pack-ice, and in the very teeth of a strong gale of wind, can be readily understood on the theory that the surface current is shallow, and the drifting colossus is only obeying the mandates of a deeper and more powerful agent.



ON HEAT CONDUCTION IN HIGHLY RAREFIED AIR.*

By William Crookes, F.R.S.

The transfer of heat across air of different densities has been examined by various experimentalists, the general result being that heat conduction is almost independent of pressure. Winkelmann (*Pogg. Ann.*, 1875, 76) measured the velocity of cooling of a thermometer in a vessel filled with the gas to be examined. The difficulty of these experiments lies in the circumstance that the cooling is caused not only by the conduction of the gas which surrounds the cooling body, but that also the currents of the gas and, above all, radiation play an important part. Winkelmann eliminated the action of currents by altering the pressure of the gas between 760 and 1 millim. (with decreasing pressure the action of gas currents becomes less); and he obtained data for eliminating the action of radiation by varying the dimensions of the outer vessel. He found that, whereas a lowering of the pressure from 760 to 91.4 millims. there was a change of only 1.4 per cent. in the value for the velocity of cooling, on further diminution of the pressure to 4.7 millims. there was a further decrease of 11 per cent., and this decrease continued when the pressure was further lowered to 1.92 millim.

About the same time Kundt and Warburg (*Pogg. Ann.*, 1874, 5) carried out similar experiments, increasing the exhaustion to much higher points, but without giving measurements of the pressure below 1 millim. They enclosed a thermometer in a glass bulb connected with a mercury pump, and heated it to a higher temperature than the highest point at which observations were to be taken; then left it to itself, and noted the time it took to fall through a certain number of degrees. They found that between 10 millims. and 1 millim. the time of cooling from 60° to 20° was independent of the pressure: on the contrary, at 150 millims. pressure the rate was one and a half times as great as at 750 millims. Many precautions were taken to secure accuracy, but no measurements of higher exhaustions being given the results lack quantitative value.

It appears, therefore, that a thermometer cools slower in a so-called vacuum than in air of atmospheric pressure. In dense air convection currents have a considerable share in the action, but the law of cooling in vacua so high that we may neglect convection has not to my knowledge been determined. Some years ago Professor Stokes suggested to me to examine this point, but finding that Kundt and Warburg were working in the same direction it was not thought worth going over the same ground, and the experiments were only tried up to a certain point, and then set aside. The data which these experiments would have given are now required for the discussion of some results on the viscosity of gases, which I hope to lay before the Society in the course of a few weeks; I have therefore completed them so as to embody the results in the form of a short paper.

An accurate thermometer with pretty open scale was enclosed in a 1½ inch glass globe, the bulb of the thermometer being in the centre, and the stem being enclosed in the tube leading from the glass globe to the pump.

Experiments were tried in two ways:—

I. The glass globe (at the various exhaustions) was immersed in nearly boiling water, and when the temperature was stationary it was taken out, wiped dry, and allowed to cool in the air, the number of seconds occupied for each sink of 5° being noted.

II. The globe was first brought to a uniform temperature in a vessel of water at 25°, and was then suddenly plunged into a large vessel of water at 65°. The bulk of hot water was such that the temperature remained sensibly the same during the continuance of each experiment. The number of seconds required for the thermometer to rise from 25° to 50° was registered as in the first case.

* Abstract of a Paper read before the Royal Society, Dec. 16, 1880.

It was found that the second form of experiment gave the most uniform results; the method by cooling being less accurate, owing to currents of air in the room, etc.

The results are embodied in the following Table:—

(Rate of Heating from 25° to 50 .)

TABLE I.

Pressure.	Temperature.	Seconds occupied in rising each 5°.	Total number of seconds occupied.
760 millims.	25°	0	0
	25 to 30	15	15
	30 to 35	18	33

	45 to 50	165	412

There are two ways in which heat can get from the glass globe to the thermometer—(1) By radiation across the intervening space; (2) by communicating an increase of motion to the molecules of the gas, which carry it to the thermometer. It is quite conceivable that a considerable part, especially in the case of heat of low refrangibility, may be transferred by "carriage," as I will call it to distinguish it from convection, which is different, and yet that we should not perceive much diminution of transference, and consequently much diminution of rate of rise with increased exhaustion, so long as we work with ordinary exhaustions up to 1 millim. or so. For if, on the one hand, there are fewer molecules impinging on the warm body (which is adverse to the carriage of heat), yet on the other the mean length of path between collisions is increased, so that the augmented motion is carried further. The number of steps by which the temperature passes from the warmer to the cooler body is diminished, and accordingly the value of each step is increased. Hence the increase in the difference of velocity before and after impact may make up for the diminution in the number of molecules impinging. It is therefore conceivable that it may not be till such high exhaustions are reached that the mean length of path between collisions becomes comparable with the diameter of the case, that further exhaustion produces a notable fall in the rate at which heat is conveyed from the case to the thermometer.

The above experiments show that there *is* a notable fall, a reduction of pressure from 5 M. to 2 M. producing twice as much fall in the rate as is obtained by the whole exhaustion from 760 millims. to 1 millim. We may legitimately infer that each additional diminution of a millionth would produce a still greater retardation of cooling, so that in such vacua as exist in planetary space the loss of heat—which in that case would only take place by radiation—would be exceedingly slow.

*M=millionth of an atmosphere.

PROFESSOR HUXLEY ON EVOLUTION.

At a recent meeting of the Zoological Society, among the papers read was one by Professor Huxley on the application of the laws of evolution to the arrangement of the vertebrata, and more particularly mammalia. The illustrations adduced were those of the history of the horse, principally, so far as is known, from the work of Professor Marsh on the Eocenes of North America. The announcement of the paper had drawn together an unusually large attendance, as it was expected that the marshalling of the facts in Professor Huxley's hands would have great interest in practically substantiating the theory of evolution, which, though foreshadowed by others, took practical shape in the work of Darwin twenty-one years ago.

Professor Huxley began by saying:—There is evidence, the value of which has not been disputed, and which, in my judgment, amounts to proof, that between the commencement of the tertiary epoch and the present time the group of the equidæ has been represented by a series of forms, of which the oldest is that which departs least from the general type of structure of the higher mammalia, while the latest is that which most widely differs from that type. In fact, the earliest known equine animal possesses four complete sub-equal digits on the fore foot, three on the hind foot; the ulna is complete and distinct from the radius; the fibula is complete and distinct from the tibia; there are 44 teeth, the full number of canines being present, and the cheek-teeth having short crowns with simple patterns and early-formed roots. The latest, on the other hand, has only one complete digit on each foot, the rest being represented by rudiments; the ulna is reduced and partially anchylosed with the radius; the fibula is still more reduced and partially anchylosed with the tibia; the canine teeth are partially or completely suppressed in the females; the first cheek-teeth usually remain undeveloped, and when they appear are very small; the other cheek-teeth have long crowns, with highly complicated patterns and late-formed roots. The equidæ of the intermediate ages exhibit intermediate characters. With respect to the interpretation of these facts two hypotheses

and only two, appear to be imaginable. The one assumes that these successive forms of equine animals have come into existence independently of one another. The other assumes that they are the result of the gradual modification undergone by the successive members of a continuous line of ancestry. As I am not aware that any zoologist maintains the first hypothesis, I do not feel called upon to discuss it. The adoption of the second, however, is equivalent to the acceptance of the doctrine of evolution so far as horses are concerned, and in the absence of evidence to the contrary, I shall suppose that it is accepted. Since the commencement of the eocene epoch, the animals which constitute the family of the equidæ have undergone processes of modification of three kinds:—1, there has been an excess of development of one part of the oldest form over another; 2, certain parts have undergone complete or partial suppression; 3, parts originally distinct have coalesced. Employing the term "law" simply in the sense of a general statement of facts ascertained by observation, I shall speak of these three processes by which the eohippus form has passed into equus as the expression of a three-fold law of evolution. It is of profound interest to remark that this law or generalized statement of the nature of the ancestral evolution of the horse, is precisely the same as that which formulates the process of individual development in animals generally, from the period at which the broad characters of the group to which an animal belongs are discernible onwards. After a mammalian embryo, for example, has taken on its general mammalian characters, its further progress towards its special form is affected by the excessive growth of one part or relation to another, by the arrest or suppression of parts already formed, and by the coalescence of parts primarily distinct. This coincidence of the laws of ancestral and individual development creates a strong confidence in the general validity of the former, and a belief that we may safely employ it in reasoning deductively from the known to the unknown. The astronomer who has determined three places of a new planet calculates its place at any epoch, however remote; and, if the law of evolution is to be depended upon, the zoologist who knows a certain length of the course of that evolution in any given case may with equal justice reason backwards to the earlier but unknown stages. Applying this method to the case of the horse, I do not see that there is any reason to doubt that the eocene equidæ were preceded by mesozoic forms, which differed from eohippus in the same way as eohippus differs from equus. And thus we are ultimately led to conceive of a first form of the equine series, which, if the law is of general validity, must need have been provided with five sub-equal digits on each plantigrade foot, with complete sub-equal antebrachial and crural bones, with clavicles, and with, as at present, 44 teeth, the cheek-teeth having short crowns and simple ridged or tuberculated patterns. Moreover, since Marsh's investigations have shown that the older forms of any given mammalian group have less developed cerebral hemispheres than the later, there is a *primâ facie* probability that this primordial hippoid had a low form of brain. Further, since the existing horse has a diffuse allantoic placentation, the primary form could not have presented a higher, and may have possessed a lower condition of the various modes by which the fœtus derives nourishment from the parent. Such an animal as this, however, would find no place in any of our systems of classification of the mammalia. It would come nearest to the lemuroidea and the insectivora, though the non-prehensile pes would separate it from the former, and the placentation from the latter group. A natural classification is one which associates together all those forms which are closely allied and separates them from the rest. But, whether in the ordinary sense of the word "alliance," or in its purely morphological sense, it is impossible to imagine a group of animals more closely allied than our primordial hippoids are with their descendants. Yet, according to existing arrangements, the ancestors would have to be placed in one order of the class of mammalia, and their descendants in another. It may be suggested that it might be as well to wait until the primordial hippoid is discovered before discussing the difficulties which will be created by its appearance. But the truth is that that problem is already pressing in another shape. Numerous "lemurs," with marked ungulate characters are being discovered in the older tertiaries of the United States and elsewhere; and no one can study the more ancient mammals with which we are already acquainted without being constantly struck with the insectivorous characters which they present. In fact, there is nothing in the dentition of either primates, carnivores, or ungulates, which is any means of deciding whether a given fossil skeleton, with skull, teeth, and limbs almost complete, ought to be ranged with the lemurs, the insectivores, the carnivores, or the ungulates. In whatever order of mammals a sufficiently long series of forms has come to light, they illustrate the three-fold law of evolution as clearly, though, perhaps, not so strikingly, as the equine series does. Carnivores, artiodactyles, and perissodactyles all tend, as we trace them back through the tertiary epoch, towards less modified forms which will fit into none of the recognized orders, but come closer to the insectivora than to any other. It would, however, be most inconvenient and misleading to term these primordial forms insectivora, the mammals so-called being themselves more or less specialized modifications of the same common type, and only, in a partial and limited sense, representatives of that type. The root of the matter appears to me to be that the palæontological facts which have come to light in the course of the last ten or fifteen years have completely broken down existing taxonomical conceptions, and that the attempts to construct fresh classification upon the old model are necessarily futile. The Cuvieran method, which all modern classifiers have followed, has been of immense value in leading to the close investigation and the clear statement of the anatomical characters of animals. But its principle, the association into sharp logical categories defined by such characters, was sapped when Von Baer showed that, in estimating the likenesses and unlikeness of the animals, development must be fully taken into account; and if the importance of individual development is admitted, that of ancestral development necessarily follows. If the end of all zoological classification is a clear and concise expression of the morphological resemblances and differences of animals, then all such resemblances must have a taxonomic value. But they fall under three heads:—(1) those of adult individuals: (2) those of successive stages of embryological development or individual evolution; (3) those of successive stages of the evolution of the species, or ancestral evolution. An arrangement is "natural," that is, logically justifiable, exactly in so far as it expresses the relations of likenesses and unlikenesses enumerated under these heads. Hence, in attempting to classify the mammalia, we must take into account not only their adult and embryogenetic characters, but their morphological relations, in so far as the several forms represent different stages of evolution. And thus, just as the persistent antagonism of Cuvier and his school to the essence of Lamarck's teachings (imperfect and objectionable as these often were in their accidents) turns out to have been a reactionary mistake, so Cuvier's no less definite repudiation of Bonnet's "*échelle*" at the present day, the existence of a "scala animantium," is a necessary consequence of the doctrine of evolution, and its establishment constitutes, I believe, the foundation of scientific taxonomy. Many years ago, in my lectures at the Royal College of Surgeon, Is particularly insisted on the central position of the insectivora among the higher mammalia; and further study of this order and of the rodentia has only strengened my conviction that any one

who is acquainted with the range of variation of structure in these groups possesses the key to every peculiarity which is met with in the primates, the carnivora, and the ungulata. Given the common plan of the insectivora and of the rodentia, and granting that the modifications of the structure of the limbs, of the brain, and of the alimentary and reproductive viscera which occur among them may exist and accumulate elsewhere, and the derivation of all eutheria from animals which, except for their diffuse placentation, would be insectivores, is a simple deduction from the law of evolution. I venture to express a confident expectation that investigation into the mammalia fauna of the mesozoic epoch will, sooner or later, fill up these blanks.

RECENT DISCOVERIES RELATING TO THE DOUBLE STARS OF THE DORPAT CATALOGUE.

By S. W. Burnham.

The distinguished Russian astronomer, Struve, published in 1837 the results of a thorough examination of the heavens for the discovery of double stars between the north pole and 15° south declination. This great catalogue, *Mensuræ Micrometricæ*, included all the double stars within these limits known prior to the observations of Struve, mainly due to the researches of Sir William Herschel, and at the time of its publication presented all that was known on this subject of astronomy. The whole number of double stars catalogued and measured by Struve was about 3000. The superiority of the telescope used at Dorpat for this class of work, over the much larger reflectors employed by the Herschels, is repeatedly shown by the observations. Many of the Herschel pairs, observed with apertures from eighteen inches to four feet, were found by Struve with the 9.6-inch refractor to be really triple, one of the components being a close pair. When Sturve's great work was published, it seemed as though there was little left for subsequent observers to do except in the way of re-observing the Struve stars. So complete and systematic had been his scrutiny of the northern heavens, it was considered that new discoveries among the stars found by Struve to be single would necessarily be of rare occurrence, and particularly after the publication, in 1850, of the Pulkowa Catalogue of 500 stars, which comprised omitted stars and later discoveries, principally by Otto Struve, the successor of his father as Director of the new Imperial Observatory. This last mentioned catalogue was much more interesting, with respect to the class of stars it contained, than the other. The Pulkowa 15-inch refractor was in every respect superior to the Dorpat glass, as well as larger. Substantially all the wide and comparatively easy pairs had been collected in *Mensuræ Micrometricæ*, so that later discoveries were necessarily either very close pairs, or the components were very unequal, and, therefore, this catalogue furnishes a much larger proportion of binary and other interesting systems. In the twenty-five years following this epoch, the whole number of double star discoveries by all observers would not exceed fifty; but many important series of measures of the Struve stars were made by English, German and Italian astronomers, and this work was steadily continued at Pulkowa, resulting in showing the periods and motions of many of the more rapid binary systems, and the relations of other double stars.

That these catalogues were really very incomplete, with reference to the number of double stars actually existing, is apparent from the fact that the writer in the last ten years has discovered at least 900 new pairs, and more than half of them with a telescope greatly inferior in size to the smallest of the instruments used by the Russian astronomers. That there was left much that was new to discover in the Struve stars will appear from the number which have been again divided by later observers. In some instances, doubtless, the close pair was missed by Struve because it was single or much closer at that time, but certainly in the great majority of instances this is improbable, and the true explanation will probably be found in the improved defining power of the later refracting telescopes. For double star work more than any other, perfect definition is of the first importance. Something may be done in observing the moon, planets, nebulæ, etc., with a large instrument of poor definition, but for the discovery or measurement of close and difficult double stars it is practically useless. It should be mentioned as a fact that every star in the following table was discovered with a refracting telescope.

The follow ng list comprises all the stars of the Dorpat Catalogue where a closer component has been discovered since the observations of Struve. More than half of these

stars have been discovered within the last eight years, and it is very probable that many new additions will be made as the large refractors now in use engage in this work. This list would be much extended by including stars to which more distant companions have been detected, but most, if not all of them, are too distant to make any physical relation probable, and are of very little interest. The first column gives a number for reference; the second column, Struve's number; the third, the name of the principal star, when found in Flamsteed or Bode; the fourth, the distance of the stars recorded by Struve; the fifth, the distance of the new star; and sixth, the name of the discoverer.

Many of the close pairs are known to be binaries, and in some cases it is probable the three stars form one system. When any change has occurred, the most recent measures of distance are given.

ASTRONOMY.

SWIFT'S COMET.

A new determination of the orbit of Swift's periodic comet has just been made by Mr. Winslow Upton of the U. S. Naval Observatory, based upon observations made at Washington, October 25, November 23, and December 22, 1880. No assumption was made with regard to the period of resolution or the eccentricity. The following are the elements obtained, and communicated to the *Astronomische Nachrichten:*

Epoch, 1880, Oct. 25. 5 Washington mean time.

$$\begin{array}{rrrrl} M & 357^\circ & 48' & 49.3'' & \\ \Omega & 296 & 41 & 55.4 & \left.\vphantom{\begin{array}{c}1\\1\\1\end{array}}\right\} 1880.0 \\ \omega & 106 & 18 & 13.8 & \\ i & 5 & 31 & 3.5 & \\ \phi & 42 & 31 & 39.7 & \\ \log a & & 0.518438 & & \\ \mu & & 592.0373'' & & \end{array}$$

The period obtained from these elements is 2189 days, which confirms the fact already announced by Mr. Chandler and others that the comet has made two revolutions since its appearance in 1869. The period obtained is also nearly identical with that given by Prof. Frisby in "SCIENCE," which he derived from observations separated by intervals of only 13 days. The comet could not have been seen at its return in 1875, as the sun was between it and the earth, and it is probable that its next return in 1886 will be unobserved for the same reason, though a careful computation which shall take into account the perturbations of the comet due to the action of the planets will be necessary to determine the question.

Professor E. S. Holden, of the Naval Observatory at Washington, has accepted the managership of the Washburn Observatory in Madison, Wis., the position made vacant by the recent death of Professor Watson. Professor Holden will enter upon his duties in a few weeks.

ASTRONOMICAL MEMORANDA:— (Approximately computed for Washington, D. C., Monday, January 24, 1881.)

Sidereal time of Mean Noon. 20h. 16m. 37s.
Equation of time. 12 29
mean noon *preceding* apparent noon.

The *Sun*, having passed the winter solstice, has reached a declination of 19° 3' south.

The *Moon* reached its Last Quarter on Jan. 22d 16h., or 4 A. M. of Jan. 23.

New Moon comes on Jan. 29d. 8h., and the First Quarter on Feb. 5d. 8h. On the morning of the 24th the Moon crosses the meridian at about a quarter of seven.

Mercury, still invisible, comes into superior conjunction with the sun on the 26th, passes to his eastern side, and becomes evening star. Mercury is in conjunction with the Moon on the morning of Jan. 30.

Venus is evening star, and throughout the month increases her distance from the sun as she approaches the earth. She follows the sun by nearly three hours and is 3° south of the equator.

Mars is morning star, rising about six o'clock, and slowly traveling away from the sun.

Jupiter, evening star, crosses the meridian about half past four:—R. A. oh. 53m., Dec. 4° 21' north.

Saturn also is evening star, having reached quadrature, or halfway from opposition to conjunction, on the 12th, when he was on the meridian at six. Saturn and Jupiter, it will be noticed, are still steadily approaching each other.

Uranus crosses the meridian at about 3 o'clock in the morning, at a declination of 7° 21' north, and cannot claim any especial attention at present.

Neptune is in R. A. 2h. 39m; Dec. 13° 36' north. It reaches quadrature on the 30th, and will be found in conjunction with the Moon on—Feb. 4th.

IN the *Popular Science Monthly* for January, 1881, Dr. Leonard Waldo gives an interesting description of the method employed at the Yale Observatory, for comparing with the standards of that institution, thermometers which have been sent there for verification by physicians, instrument makers and others. He calls attention to the fact that thermometers, even if from makers of established reputation, are liable to errors much greater than is commonly supposed, and he points out the necessity of having such errors carefully determined.

WE learn from the *Comptes Rendus* that Janssen has made preparations at Meudon to repeat Dr. Draper's experiments on the photography of the Nebula in Orion, and that for this purpose he proposes to construct upon a large scale a telescope of short focus quite similar to the one with which he obtained a very luminous spectrum of the Corona, in 1871. Janssen has also made some experiments in photographing the chromosphere. The exposure is continued so long that the solar image becomes positive to the very circumference, without going beyond it. The chromosphere is then shown in the form of a dark ring with a thickness of 8" or 10". He has compared positive and negative solar photographs taken on the same day and with the same instrument, and the measurement of the diameter shows that the dark ring in question is wholly outside of the solar disk.

DR. WARREN DE LA RUE has been elected a corresponding member of the Paris Academy of Sciences in the section of Astronomy, and M. Sella a corresponding member in the section of Mineralogy.

THE Rumford medal of the Royal Society has been awarded to Dr. William Huggins for his work on celestial spectroscopy, and the Copley medal to Prof. J. J. Sylvester of Johns Hopkins University for researches in pure mathematics. W. C. W.

ECLIPSE OF THE SUN.

To the Editor of "SCIENCE:"

I would like to add a sentence to the fourth paragraph of my letter in last week's "SCIENCE" giving my observations of the recent partial eclipse of the sun. After the words "solar limb" I would add, "on the eastern side of the sun the phenomenon was considerably less prominent and only visible at the time of greatest obscuration, and when the slit was quite close to the sun's limb."

L. TROUVELOT.

CAMBRIDGE, January 12, 1881.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, JANUARY 29, 1881.

THE advantages of having a good public library in a large city are so obvious that it appears incomprehensible that the most important city in the United States is practically without such an institution.

The city of New York appears to have been fortunate in being made the recipient of munificent testimentary gifts for the purpose of founding a great public library suited to the needs of such a community, but also unexceptionally unfortunate in the disposition of the funds so bequeathed.

The Astor Library contains a collection of books which have been most judiciously selected to form the nucleus of a good public library, and one peculiarly suited to the needs of those residing in such a city as New York. Unfortunately, the trustees of the library permit its use only between the hours of 10 A.M. and 4 P. M., thus practically shutting out the majority of those who desire to consult the literary treasures it contains.

Of the Lennox Library, recently bequeathed to the citizens of New York, it may be premature to speak; possibly in time its doors may be open to the public; but under what conditions and restrictions can only be conjectured from the eccentric formalities of the past.

Thus with the Astor Library open for a few fashionable hours during the day, and the Lennox Library closed altogether, the public of New York finds itself after four o'clock, P. M., daily, and during the whole of Sunday, without a free public library. Such a state of things is not creditable to the largest and most important city in this Republic, and should not continue a day longer.

The good policy of establishing a public library for New York city, which shall be under the full control of the city authorities, is daily becoming more apparent, and we trust the time is not distant when the wishes of the people in this respect may be fully realized.

A letter will be found in another page of this issue relating to our notice of Dr. Beard's lecture on "Mesmeric Trance." The writer is not correct in stating that we threw a doubt on the genuineness of the "phenomena, as a whole," as on the contrary our remarks questioned the integrity of the "subjects" produced by Dr. Beard. These men and boys, since the lecture in question, have been nightly performing the same tricks in a room on Sixth avenue, the advertisement for which is headed "Marvels and Fun of Mesmerism." The propriety of bringing such "subjects" before the New York Academy of Sciences, may well be questioned, and so far from accepting their performances as genuine exhibitions of the phenomena of Hypnotism, we apprehend the closest scrutiny should be made to test the genuineness of their acts.

Professor Hitchcock admits that he and others observed what appeared to us as evidence of collusion between Dr. Beard and his subjects, but objects to our having pointed out these facts, without having first permitted Dr. Beard to give his explanation of them. This amounts to a request to suppress all criticism, except that controlled by the person criticised, which appears to us one of the least inviting methods of arriving at the truth.

The subject is one of undoubted interest, and as we do not wish to prejudice the question, we defer any detailed reply to Professor Hitchcock's letter until others have had an opportunity of expressing their views. Our columns will be open to any correspondent who can add to our knowledge of this subject, or who can give a rational explanation of the phenomenon of Hypnotism.

SCIENTIFIC SOCIETIES IN WASHINGTON.

THE ANTHROPOLOGICAL SOCIETY.

NEW OFFICERS ELECTED AND A CHANGE OF LOCATION AGREED UPON.

The Anthropological Society met at the Smithsonian Institution on the evening of January 18th, Major J. W. Powell, the president, in the chair. The following new members were elected: Dr. A. F. A. King, Dr. William Lee, and Mr. Ivan Petroff for active membership, and Mr. J. C. Tache and B. B. Redding for corresponding membership. It being the evening of the annual election, no papers were read. A motion to remove from the present location to the lecture-hall of the National Medical College of the Columbian University was introduced by a committee of the council, and adopted by the society.

The election of officers to serve during the ensuing year resulted as follows: President, Major J. W. Powell; vice-presidents, Colonel Garrick Mallery, Dr. George A. Otis, Professor O. T. Mason, Dr. H. C. Yarrow; corres-

ponding secretary, C. C. Royce; recording secretary, Lester F. Ward; treasurer, J. Howard Gore; curator, Dr. W. J. Hoffman; council, President J. C. Welling, Professor E. A. Fay, Dr. J. Meredith Toner, Mr. F. A. Seely, Mr. Miles Rock, Mr. H. L. Thomas.

THE BIOLOGICAL SOCIETY OF WASHINGTON.

On the first of December last, another society was organized for the study of the Biological sciences which, after completing its organization, elected the following officers for the ensuing year: President, Theodore Gill; vice-presidents, C. V. Riley, J. W. Chickering, Henry Ulke, Lester F. Ward; secretaries, G. Browne Goode, Richard Rathburn; treasurer, Robert Ridgway; council, George Vasey, O. T. Mason, J. H. Comstock, and Drs. Schafer and A. F. A. King. Professor S. F. Baird was elected an honorary member. Dr. Frank H. Baker, Mr. H. H. Birney and Mr. C. W. Scudder were elected to active membership. Professor L. F. Ward read a paper entitled "The Flora Columbiana of 1830 and 1880," in which a comparison was made between the lists of plants recorded as growing in the District of Columbia in 1830 in Brereton's "Flora," and the lists as now known to the botanists of the District. Mr. Ulke spoke of the occurrence in the District of many species of beetles, before known only in Alaska and other remote localities. Professor Jordan read a paper on "The Salmon of the California Coast," which contained many new and important facts regarding their habits and economic value. The annual address will be delivered at the next meeting by Professor Theodore Gill. A paper was also read by Professor Tarleton H. Bean on "An Excursion to the Northern Coast of Alaska."

CHEMICAL SOCIETIES.

The January *Conversazione* of the American Chemical Society was held at the rooms of the Society on Monday evening, January 17. The Vice-President, Dr. Albert R. Leeds, of the Stevens Institute, exhibited a new modification of Dinitro-orcine and certain of its salts. These salts were originally prepared by Professor Leeds at his own laboratory in the course of his investigations of Hyponitric Anhydride in organic substances.

Specimens of Dibenzole and Diphenyle were also exhibited by the same gentleman. Several of the members took advantage of the occasion to visit the laboratory and see the recently patented electrical inventions of Dr. O. Lugo.

The next and regular meeting will take place on the first Monday of February, the 7th prox.

The Chemical Society of Paris announces that among the vice-presidents, according to the constitution, the president shall be chosen from the following gentlemen; M. M. Grimaux, Salet and Berthelot, and that the Council nominates M. M. Grimaux and Salet; therefore M. Berthelot will remain as vice-president during 1881, and in consequence of the regretted decease of M. Personne, M. Berthelot will be the only occupant of that office.

The German Chemical Society at their annual re-union increased the dues of the non-resident members from 15 to 20 marks. This action has been in contemplation for several years, and has now been definitely settled.

M. B.

THE French Association for the Advancement of Science is to hold its next meeting in the city of Algiers, on the 14th of April. The people and authorities of the city are making preparations to give the Association a fitting welcome, and liberal appropriations have been made by the Council for organizing the meeting, to entertain the members and their friends.

THE UNITY OF NATURE.

BY THE DUKE OF ARGYLL.

V.

ON THE TRUTHFULNESS OF HUMAN KNOWLEDGE CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

But another nightmare meets us here—another suggestion of hopeless doubt respecting the very possibility of knowledge touching questions such as these. Nay, it is the suggestion of a doubt even more discouraging—for it is a suggestion that these questions may probably be in themselves absurd—assuming the existence of relations among things which do not exist at all—relations indeed of which we have some experience in ourselves, but which have no counterpart in the system of Nature. The suggestion, in short, is not merely that the answer to these questions is inaccessible, but that there is no answer at all. The objection is a fundamental one, and is summed up in the epithet applied to all such inquiries —that they are anthropomorphic. They assume authorship in a personal sense, which is a purely human idea—they assume causation, which is another human idea—and they assume the use of means for the attainment of ends, which also is purely human. It is assumed by some persons as a thing in itself absurd that we should thus shape our conceptions of the ruling power in Nature, or of a Divine Being, upon the conscious knowledge we have of our own nature and attributes. Anthropomorphism is the phrase employed to condemn this method of conception—an opprobrious epithet, as it were, which is attached to every endeavor to bring the higher attributes of the human mind into any recognizable relation with the supreme agencies in Nature. The central idea of those who use it seems to be that there is nothing human there; and that when we think we see it there, we are like some foolish beast wondering at its own shadow. The proposition which is really involved when stated nakedly is this: that there is no Mind in Nature having any relation with, or similitude to, our own, and that all our fancied recognitions of intellectual operations like our own in the order of the Universe are delusive imaginations.

The denial of what is called "The Supernatural" is the same doctrine in another form. The connection may not be evident at first sight, but it arises from the fact that the human mind is really the type of the Supernatural. It would be well if this word were altogether banished from our vocabulary. It assumes that we know all that "Nature" contains, and that we can pronounce with certainty on what can and what cannot be found there. Or else it assumes that Nature is limited to purely physical agencies, and that our own mind is a power and agency wholly separate and distinct from these. There might indeed be no harm in this limitation of the word if it could be consistently adhered to in all the terms of any argument involving its use. We are all quite accustomed to think of Man as not belonging to Nature at all—as the one thing or Being which is contradistinguished from Nature. This is implied in the commonest use of language, as when we contrast the works of Man with the works of Nature. The same idea is almost unconsciously involved in language which is intended to be strictly philosophical, and in the most careful utterances of our most distinguished scientific men. Thus Professor Tyndall, in his Belfast address to the British Association, uses these words: "Our earliest historic ancestors fell back also upon experience, but with this difference, that the particular experiences which furnished the weft and woof of their theories were drawn, not from the study of Nature, but from what lay much closer to them—the observation of men." Here Man is especially contradistinguished from Nature; and accordingly we find in the next sentence that this idea is connected with the error of seeing our-

selves—that is, the Supernatural in Nature. "Their theories," the Professor goes on to say, "accordingly took an anthropomorphic form." Further on, in the same address, the same antithesis is still more distinctly expressed thus: "If Mr. Darwin rejects the notion of creative power acting after human fashion, it certainly is not because he is unacquainted with the numberless exquisite adaptations on which the notions of a supernatural artificer is founded." Here we see that the idea of "acting after human fashion," is treated as synonymous with the idea of a supernatural artificer; and the same identification may be observed running throughout the language which is commonly employed to condemn Anthropomorphism and the Supernatural.

The two propositions, therefore, which are really involved in the thorough-going denial of Anthropomorphism and the Supernatural are the following: 1st, that there is nothing above or outside of Nature as we see and know it; 2nd, that in the system of Nature, as thus seen and known, there is no mind having analogies with our own.

Surely these propositions have been refuted the moment the definition of them has been attained. We have only to observe, in the first place, the strange and anomalous position in which it places Man. As regards at least the higher faculties of his mind, he is allowed no place in Nature, and no fellowship with any other thing or any other Being outside of Nature. He is absolutely alone—out of all relation with the Universe around him, and under a complete delusion when he sees in any part of it any mental homologies with his own intelligence, or with his own will, or with his own affections. Does this absolute solitariness of position as regards the higher attributes of Man—does it sound reasonable, or possible, or consistent with some of the most fundamental conceptions of science? How, for example, does it accord with that great conception whose truth and sweep become every day more apparent—the Unity of Nature?

How can it be true that Man is so outside of that unity that the very notion of seeing anything like himself in it is the greatest of all philosophical heresies? Does not the very possibility of science consist in the possibility of reducing all natural phenomena to purely mental conceptions, which must be related to the intellect of Man when they are worked out and apprehended by it? And if, according to the latest theories, Man is himself a Product of Evolution; and is therefore, in every atom of his body and in every function of his mind, a part and a child of Nature, is it not in the highest degree illogical so to separate him from it as to condemn him for seeing in it some image of himself? If he is its product and its child, is it not certain that he is right when he sees and feels the indissoluble bonds of unity which unite him to the great system of things in which he lives?

This fundamental inconsistency in the Agnostic philosophy becomes all the more remarkable when we find that the very men who tell us we are not one with anything above us, are the same who insist that we are one with everything beneath us. Whatever there is in us or about us which is purely animal we may see everywhere; but whatever there is in us purely intellectual and moral, we delude ourselves if we think we see it anywhere. There are abundant homologies between our bodies and the bodies of the beasts, but there are no homologies between our minds and any Mind which lives or manifests itself in Nature. Our livers and our lungs, our vertebræ and our nervous systems, are identical in origin and in function with those of the living creatures round us; but there is nothing in Nature or above it which corresponds to our forethought, or design, or purpose—to our love of the good or our admiration of the beautiful—to our indignation with the wicked, or to our pity for the suffering and the fallen. I venture to think that no system of philosophy that has ever been taught on earth lies under such a weight of antecedent improbability; and this improbability increases in direct proportion to the success of science in tracing the Unity of Nature, and in showing step by step how its laws and their results can be brought more and more into direct relation with the Mind and intellect of Man.

Let us test this philosophy from another point of view, and see how far it is consistent with our advancing knowledge of those combinations of natural force by which the system of the physical Universe appears to be sustained.

We may often see in the writings of our great physical teachers of the present day reference made to a celebrated phrase of the old and abandoned school of Aristotelian physics—a phrase invented by that old school to express a familiar fact—that it is extremely difficult, if not absolutely impossible, to produce a perfect vacuum—that is to say, a space which shall be absolutely empty. The phase was this: "Nature abhors a vacuum." It is now continually held up as a perfect example and type of the habit of thought which vitiates all true physical reasoning. Now let us observe what this error is. As a forcible and picturesque way of expressing a physical truth—that the difficulty of producing a vacuum is extreme, that Nature sets, as it were, her face against her doing it—the phrase is a good one, and conveys an excellent idea of the general fact. Sir W. Grove says of it, that it is an "aphorism, which, though caviled at and ridiculed by the self-sufficiency of some modern philosophers, contains in a terse though somewhat metaphorical form the expression of a comprehensive truth." But there is this error in the phrase (if indeed it was or ever could be literally understood)—that it gives for the general fact a wrong cause, inasmuch as it ascribes to the material and inanimate forces of Nature, whose simple pressures are concerned in the result, certain dispositions that are known to us as affections of Mind alone. In short, it ascribes to the mere elementary forces of Matter—not to a living agency using these as tools, but to mere material force—the attributes of Mind.

Now it is well worthy of remark, that, so far as this error is concerned, the language of physical science is full of it—steeped in it; and that in this sense it is chargeable with a kind of anthropomorphism which is really open to the gravest objection. To see Mind in Nature, or, according as Nature may be defined, to see Mind outside of Nature, acknowledging it to be Mind, and treating it as such—this is one thing—and this is the true and legitimate anthropomorphism which some physicists denounce. But to see Mind in material forces alone, and to ascribe its attributes to them—this is equally anthropomorphism, but a form of it which is indeed open to all the objections they express. This, nevertheless, is the anthropomorphism which gives habitually its coloring to their thoughts and its spirit to their language.

Let me explain what I mean by some examples. I will take, first, the theory of development, or the derivative hypothesis, which, as applied to the history of animal life, is now accepted by a large number of scientific men, if not as certainly true, at least as an hypothesis which comes nearer than any other to the truth. Whether that theory be true or not, it is a theory saturated throughout with the ideas of utility and fitness, and of adaptation, as the governing principles and causes of the harmony of Nature. Its central conception is, that in the history of organic life changes have somehow always come about exactly in proportion as the need of them arose. But how is it that the laws of growth are so correlated with utility that they should in this manner work together? Why should varied and increasing utility operate in the requisite direction of varied and increasing developments? The connection is not one of logical necessity. Not only can we conceive it otherwise, but we know it is otherwise beyond certain bounds and limits. It is not an universal law that organic growths arise in proportion to all needs, or are strengthened by all exertion. It is a law prevailing

only within certain limits; and it is not possible to describe the facts concerning it without employing the language which is expressive of mental purpose.

Accordingly, Mr. Darwin himself does use this language perpetually, and to an extent far exceeding that in which it is used by almost any other natural philosopher. He does not use it with any theological purpose nor in connection with any metaphysical speculation. He uses it simply and naturally for no other reason than that he cannot help it. The correlation of natural forces, so adjusted as to work together for the production of use in the functions—for the enjoyments and for the beauty—of life, this is the central idea of his system; and it is an idea which cannot be worked out in detail without habitual use of the language which is molded on our own consciousness of the mental powers by which all our own adjustments are achieved. This is what, perhaps, the greatest observer that has ever lived cannot help observing in Nature; and so his language is thoroughly anthropomorphic. Seeing in the methods pursued in Nature a constant embodiment of his own intellectual conceptions, and a close analogy with the methods which his own mind recognizes as "contrivance," he rightly uses the forms of expression which convey the work of Mind. "Rightly," I say, provided the full scope and meaning of this language be not repudiated. I do not mean that naturalists should be always following up their language to theological conclusions, or that any fault should be found with them when they stop where the sphere of mere physical observation terminates. But those who seek to remodel philosophy upon the results of that observation cannot consistently borrow all the advantage of anthropomorphic language, and then denounce it when it carries them beyond the point at which they desire to stop. If in the words which we recognize as best describing the facts of Nature there be elements of meaning to which their whole force and descriptive power is due, then these elements of meaning must be admitted as essential to a just conception and to a true interpretation of what we see. The analogies which help us to understand the works of Nature are not, as it were, foreign material imported into the facts, but are part of these facts, and constitute the light which shines from them upon the intellect of Man. In exact proportion as we believe that intellect to be a product of Nature, and to be united to it by indissoluble ties of birth, of structure, and of function, in the same proportion may we be sure that its organs of vision are adjusted to the realities of the world, and that its innate perceptions of analogy and resemblance have a close relation to the truth. The theory of Development is not only consistent with teleological explanation, but it is founded on teleology, and on nothing else. It sees in everything the results of a system which is ever acting for the best, always producing something more perfect or more beautiful than before, and incessantly eliminating whatever is faulty or less perfectly adapted to every new condition. Professor Tyndall himself cannot describe this system without using the most intensely anthropomorphic language, "The continued effort of animated nature is to improve its conditions and raise itself to a loftier level."

Again I say, it is quite right to use this language, provided its ultimate reference to Mind be admitted and not repudiated. But if this language be persistently applied and philosophically defended as applicable to material force, otherwise than as the instrument and tool of Mind, then it is language involving far more than the absurdity of the old mediæval phrase that "Nature abhors a vacuum." It ceases to be a mere picturesque expression, and becomes a definite ascription to Matter of the highest attributes of Mind. If Nature cannot feel abhorrence, neither can it cherish aspirations. If it cannot hate, neither can it love, nor contrive, nor adjust, nor look to the future, nor think about "loftier levels" there.

Professor Tyndall in the same address has given us an interesting anecdote of a very celebrated man whom the world has lately lost. He tells us that he heard the great Swiss naturalist, Agassiz, express an almost sad surprise that the Darwinian theory should have been so extensively accepted by the best intellects of our time. And this surprise seems again in some measure to have surprised Professor Tyndall. Now it so happens that I have perhaps the means of explaining the real difficulty felt by Agassiz in accepting the modern theory of evolution. I had not seen that distinguished man for nearly five-and-thirty years. But he was one of those gifted beings who stamp an indelible impression on the memory; and in 1842 he had left an enthusiastic letter on my father's table at Inverary on finding it largely occupied by scientific works. Across that long interval of time I ventured lately to seek a renewal of acquaintance, and during the year which proved to be the last of his life, I asked him some questions on his own views on the history and origin of organic forms. In his reply Agassiz sums up in the following words his objection to the theory of Natural Selection as affording any satisfying explanation of the facts for which it professes to account:—"The truth is that Life has all the wealth of endowment of the most comprehensive mental manifestations, and none of the simplicity of physical phenomena."

Here we have the testimony of another among the very greatest of modern observers that wealth—immense and immeasureable wealth—of Mind is the one fact above all others observable in Nature, and especially in the adaptations of organic life. It was because he could see no adequate place or room reserved for this fact in the theory of development that Agassiz rejected it as not satisfying the conditions of the problem to be solved. Possibly this may be the fault of the forms in which it has been propounded, and of the strenuous endeavors of many of its supporters to shut out all interpretations of a higher kind. But of this we may be sure, that if men should indeed ultimately become convinced that species have been all born just as individuals are now all born, and that such has been the universal method of creation, this conviction will not only be found to be soluble, so to speak, in the old beliefs respecting a creative Mind, but it will be unintelligible and inconceivable without them, so that men in describing the history and aim and direction of evolution, will be compelled to use substantially the same language in which they have hitherto spoken of the history of creation.

Mr. Mivart has indeed remarked in a very able work,[1] that the teleological language used so freely by Mr. Darwin and others is purely metaphorical. But for what purpose are metaphors used? Is it not as a means of making plain to our own understandings the principles of things, and of tracing amid the varieties of phenomena the essential unities of Nature? In this sense all language is full of metaphor, being indeed composed of little else. That is to say, the whole structure and architecture of language consists of words which transfer and apply to one sphere of investigation ideas which have been derived from another, because there also the same ideas are seen to be expressed, only under some difference of form. Accordingly when naturalists, describing plants or animals, use metaphorically the language of contrivance to describe the adaptations of function, they must use it because they feel it to be a help in the understanding of the facts. When, for example, we are told that flowers are constructed in a peculiar manner "in order that" they may catch the probosces of moths or the beaks of bees, and that this adaptation again is necessary "in order that" these insects should carry the fertilizing pollen from flower to flower, nothing more may be immediately intended by the writer than that all this elaborate mechanism does as a matter of fact attain

[1] "Genesis of Species."

this end, and that it may fitly be described "as if" it had been arranged "in order that" these things might happen. But this use of language is none the less an acknowledgment of the truth that the facts of Nature are best brought home and explained to the understanding by stating them in terms of the relation which they obviously bear to the familiar operations of our own mind and spirit.

And this is the invariable result of all physical inquiry. In this sense Nature is essentialy anthropomorphic. Man sees his own mind reflected in it—his own, not in quantity but in quality—his own fundamental attributes of intellect, and, to a wonderful and mysterious degree, even his own methods of operation.

It is really curious and instructive to observe how even those who struggle hardest to avoid the language of anthropomorphism in the interpretations of Nature are compelled to make use of the analogies of our own mental operations as the only possible exponents of what we see. Let us look, for example, at the definition of Life given by Mr. Herbert Spencer. It is a very old endeavor to construct such definitions, and not a very profitable one: inasmuch as Life is only known to us as itself, and all attempts to reduce it to other conceptions are generally mere playing with empty words. But it is not without instruction to observe that Mr. Spencer's laborious analysis comes to this: "Life is the continuous adjustment of internal relations to external relations." Bare, abstract, and evasive of characteristic facts as this formula is, it does contain at least one definite idea as to how Life comes to be. Life is an "adjustment." This is a purely anthropomorphic conception, conveying the idea of that kind of co-ordination between different powers or elements which is the result of constructive purpose. I have already pointed out in a former chapter that all combinations are not adjustments. The whole force and meaning of the word consists in its reference to intentional arrangement. No combination can properly be called an adjustment if it be purely accidental. When, therefore, Life is represented as an adjustment, this is the mental image which is reproduced; and in so far as it does reproduce this idea, and does consciously express it, the formula has at least some intelligible meaning. If, indeed, it has any plausibility or approach to truth at all, this is the element in it from which this plausibillty is derived.

We may take another case. Mr. Matthew Arnold has invented a new phrase for that conception of a Divine Being which alone, he thinks, can be justified by such evidence as we possess. And what is that phrase? "The Eternal, not ourselves, which makes for righteousness." Surely whatever meaning there may in this artificial and cumbrous phrase is entirely derived from its anthropomorphism. An agency which "makes for" something —that something, too, being in the future, and being also in itself an abstract, moral, and intellectual conception—what can such an agency be conceived to be? "Making for" an object of any kind is a purely human image—an image, too, derived primarily not from the highest efforts of human Will, but from those which are represented in the exercises of the body, and the skill with which, in athletic contentions, some distant goal may be reached and won. Such is the attempt of a very eminent man to instruct us how we are to think of God without seeing in Him or in His word anything analogous to our own thought and work.

Nor is it wonderful that this attempt should fail, when we consider what it is an attempt to do—to establish an absolute separation between Man and Nature; to set up Man as something above Nature, and outside of it; and yet to affirm that there is no other Being, and no other Intelligence in a like position. And if anything can render this attempt more unreasonable, it must be the urther attempt to reach this result through science—science, the very possibility of which depends upon and consists in the possibility of reducing all natural phenomena within the terms of human thought, so that its highest generalizations are always the most abstract intellectual conceptions. Science is the systematic knowledge of relations. But that which perceives relations must be itself related. All explanations consist in nothing else than in establishing the relation which some order of external facts bears to some corresponding order of thought; and it follows from this truth, that the highest explanations of phenomena must always be those which establish such relations with the highest faculties of our nature. Professor Tyndall, in another part of his Belfast address, like many other writers of the present day, goes the length of saying that the great test of physical truth is what may be called its "representability,"—that is to say, the degree in which a given physical conception can, from the analogies of experience, be represented in thought. But if our power of picturing a physical fact distinctly be indeed an indication of a true physical analogy, how much more distinctly than any physical fact can we picture the characteristic workings of our own mental constitution. Yet these are the conceptions which, we are told, we are not to cherish, because they are anthropomorphic—or, in other words, because of the very fact that they are so familiar to us, and their mental representability is so complete.

Some, indeed, of our physical teachers, conscious of this necessary and involuntary anthropomorphism of human thought and speech, struggle hard to expel it by inventing phrases which shall as far as possible avoid it. But it is well worthy of observation that, in exact proportion as these phrases do avoid it, they become incompetent to describe fully the facts of science. For example, take those incipient changes in the substance of an egg by which the organs of the future animal are successively laid down—changes which have all reference to a purely purposive adaptation of that substance to the future discharge of separate and special functions. I have already referred[2] to the fact that these changes are now commonly described as "differentiations," an abstract expression which simply means the establishment of differences, without any reference to the peculiar nature of those differences, or their relations to each other and to the whole. But the inadequacy of this word to express the facts is surely obvious. The process of dissolution and decay are processes of differentiation as much as the process of growth and adaptation to living functions. Blood is differentiated just as much when, upon being spilt upon the ground, it separates into its inorganic elements, as when, circulating in the vessels, it bathes and feeds the various tissues of the living body. But these two operations are not only different, but absolutely opposite in kind, and there does not seem to be much light in that philosophy which insists on using the same formula of expression to describe them both. It is a phrase which empties the facts, as we can see and know them, of all that is special in our knowledge of them. It is possible, no doubt, by this and other similar artifices of language, so to deprive them—or at least to appear to deprive them—of their highest mental characters. More foolish than the fabled ostrich, we may try to shut our eyes against our own perceptions, or refuse to register them in our language—resorting, for the sake of evasion, to some juggleries of speech. "Potential existence" is another of those vague abstract conceptions which may be, and is, employed for a like purpose. It may be applied indiscriminately to a mere slumbering force, or to an unfulfilled intention, or to an undeveloped mental faculty, or to an elaborate preparation of foresight and design. If we desire to take refuge from the necessity of forming any

[2] "SCIENCE," Vol. I., p. 181.

distinct conceptions, such phrases are eminently convenient for the purpose, whilst under cover of them we may cheat ourselves into the belief that we have got hold of some definite idea, and perhaps even of an important truth.

All who are puzzled and perplexed by the prevalent teaching on these high matters should subject the language in which it is conveyed to a careful, systematic, and close analysis. It will be found to fall within one or another of these three classes:—First, there is the phraseology of those who, without any thought either of theological dogma or of philosophical speculation, are, above all things, observers, and who describe the facts they see in whatever language appears most fully and most naturally to convey what they see to others. The language of such men is what Mr. Darwin's language almost always is—eminently teleological and anthropomorphic. Next, there is the language of those who purposely shut out this element of thought, and condemn it as unscientific. The language of this class is full of the vague abstract phrases to which I have referred—"differentiation"—"molecular change"—"harmony with environment," and others of a like kind—phrases which, in exact proportion to their abstract character, are evasive, and fall short of describing what is really seen. Lastly we have the language of those who habitually ascribe to Matter the properties of Mind; using this language not metaphorically, like the old Aristotelians whom they despise, but literally—declaring that Mind, as we know it, must be considered as having been contained "potentially" in Matter; and was once nothing but a cosmic vapor or a fiery cloud. Well may Professor Tyndall call upon us "radically to change our notions of Matter," if this be a true view of it; for in this view it becomes equivalent to "Nature" in that largest and widest interpretation to which I referred at the close of the last chapter—viz., that in which Nature is understood as the "Sum of all Existence." But if this philosophy be true, let us at least cease to condemn, as the type of all absurdity, the old mediæval explanations of material phenomena, which ascribe to them affections of the mind. If Matter be so widened in meaning as to be the mother and source of Mind, it must surely be right and safe enough to see in it those dispositions and phenomena which are nothing but its product in ourselves.

The truth is, that this conception of Matter and of Nature, which is associated with vehement denunciations of anthropomorphism, is itself founded on nothing else but anthropomorphism pushed to its very farthest limit. It is entirely derived from and founded on the fact that mind, as we see it in ourselves, is in this world inseparably connected with a material organism, and on the further assumption that Mind is inconceivable or cannot be inferred except in the same connection. This would be a very unsafe conclusion, even if the connection between our bodies and our minds were of such a nature that we could not conceive the separation of the two. But so far is this from being the case, that, as Professor Tyndall most truly says, "it is a connection which we know only as an inexplicable fact, and we try to soar in a vacuum when we seek to comprehend it." The universal testimony of human speech—that sure record of the deepest metaphysical truths—prove that we cannot but think of the body and the mind as separate—of the mind as our proper selves, and of the body as indeed external to it. Let us never forget that Life, as we know it here below, is the antecedent or the cause of organization, and not its product; that the peculiar combinations of matter which are the homes and abodes of Life are prepared and shaped under the control and guidance of that mysterious power which we know as vitality; and that no discovery of science has ever been able to reduce it to a lower level, or to identify it with any purely material force. And, lastly, we must remember, that even if it be true that Life and Mind have some inseparable connection with the forces which are known to us as material, this would not make the supreme agencies in Nature, or Nature as a whole, less anthropomorphic, but greatly more; so that it would, if possible, be even more unreasonable than it is now to condemn man when he sees in Nature a Mind having real analogies with his own.

And now what is the result of this argument—what is its scope and bearing? Truly it is a very wide scope indeed—nothing less than this: that nothing in philosophy, in theology, in belief, can be reasonably rejected or condemned on the sole ground that it is anthropomorphic. That is to say, no adverse presumption can arise against any conception, or any idea, or any doctrine on the mere ground that it rests on the analogies of human thought. This is a position—purely negative and defensive though it be—from which we cannot be dislodged, and which holds under its destructive fire a thousand different avenues of attack.

But this is not all. Another result of the same argument is to establish a presumption the other way. All the analogies of human thought are in themselves analogies of Nature, and in proportion as they are built up or are perceived by Mind in its higher attributes and work, they are part and parcel of natural truth. Man—he whom the Greeks called Anthropos, because, as it has been supposed, he is the only Being whose look is upwards—Man is a part of Nature, and no artificial definitions can separate him from it. And yet in another sense it is true that Man is above Nature—outside of it; and in this aspect he is the very type and image of the "Supernatural." The instinct which sees this image in him is a true instinct, and the consequent desire of atheistic philosophy to banish anthropomorphism from our conceptions is dictated by an obvious logical necessity. But in this necessity the system is self-condemned. Every advance of science is a new testimony to the supremacy of Mind, and to the correspondence between the mind of Man and the mind which is supreme in Nature. Nor yet will it be possible, in the face of science, to revive that Nature-worship which breathes in so many of the old religions of mankind. For in exalting Mind, science is ever making plainer and plainer the inferior position of the purely physical aspects of Nature—the vague character of what we know as Matter and material force. Has not science, for example, even in these last few years, rendered forever impossible one of the oldest and most natural of the idolatries of the world? It has disclosed to us the physical constitution of the Sun—that great heavenly body which is one of the chief proximate causes of all that we see and enjoy on earth, and which has seemed most naturally the very image of the Godhead to millions of the human race. We now know the sun to be simply a very large globe of solid and of gaseous matter, in a state of fierce and flaming incandescence. No man can worship a ball of fire, however big; nor can he feel grateful to it, nor love it, nor adore it, even though its beams be to him the very light of life. Neither in it nor in the mere physical forces of which it is the centre, can we see anything approaching to the rank and dignity of even the humblest human heart. "What know we greater than the soul?" It is only when we come to think of the co-ordination and adjustment of these physical forces as part of the mechanism of the heavens—it is only, in short, when we recognize the mental—that is, the anthropomorphic—element, that the Universe becomes glorious and intelligible, as indeed a Cosmos; a system of order and beauty adapted to the various ends which we see actually attained, and to a thousand others which we can only guess. No philosophy can be true which allows that we see in Nature the most intimate relations with our intellectual conceptions of Space and Time and Force, but denies that we

can ever see any similar relation with our conceptions of purpose and design, or with those still higher conceptions which are embodied in our sense of justice and in our love of righteousness, and in our admiration of the "quality of mercy." These elements in the mind of Man are not less certain than others to have some correlative in the Mind which rules in Nature. Assuredly, in the supreme government of the Universe these are not less likely than other parts of our mental constitution to have some part of the natural system related to them—so related that the knowledge of it shall be at once their interpretation and fulfillment. Neither brute matter nor inanimate force can supply either the one or the other. If there be one truth more certain than another, one conclusion more securely founded than another, not on reason only, but on every other faculty of our nature, it is this—that there is nothing but mind that we can respect; nothing but heart that we can love; nothing but a perfect combination of the two that we can adore.

And yet it cannot be denied that among the many difficulties and the many mysteries by which we are surrounded, perhaps the greatest of all difficulties and the deepest of all mysteries concerns the limits within which we can, and beyond which we cannot, suppose that we bear the image of Him who is the source of life. It seems as if on either side our thoughts are in danger of doing some affront to the Majesty of heaven—on the one hand, if we suppose the Creator to have made us with an intense desire to know Him, but yet destitute of any faculties capable of forming even the faintest conception of His nature; on the other hand, if we suppose that creatures such as (only too well) we know ourselves to be, can image the High and the Holy One who inhabiteth Eternity. Both these aspects of the truth are vividly represented in the language of those who "at sundry times and in divers manners" have spoken most powerfully to the world upon Divine things. On the one hand we have such strong but simple images as those which represent the Almighty as "walking in the garden in the cool of the day," or as speaking to the Jewish lawgiver "face to face, as a man speaketh to his friend;" on the other hand we have the solemn and emphatic declaration of St. John that "no man hath seen God at any time." In the sublime poetry of Job we have at once the most touching and almost despairing complaints of the inaccessibility and inscrutability of God, and also the most absolute confidence in such a knowledge of His character as to support and justify unbounded trust. In the Psalms we have these words addressed to the wicked as conveying the most severe rebuke, "Thou thoughtest that I was altogether such an one as thyself."

And perhaps this word "altogether" indicates better than any other the true reconciliation of apparent contradictions. In the far higher light which Christianity claims to have thrown on the relations of Man to God, the same solution is in clearer terms presented to us. "Knowing in part and prophesying in part," "Seeing through a glass darkly," and many other forms of expression, imply at once the reality and yet partial character of the truths which on these high matters our faculties enable us to attain. And this idea is not only consistent, but is inseparably connected with that sense of limitation which we have already seen to be one of the most remarkable and significant facts connected with our mental constitution. There is not one of the higher powers of our mind in respect of which we do not feel that "we are tied and bound by the weight of our infirmities." Therefore we can have no difficulty in conceiving all our own powers exalted to an indefinite degree. And thus it is that although all goodness, and power, and knowledge, must, in respect to quality, be conceived of as we know them in ourselves, it does not follow that they can only be conceived of according to the measures which we ourselves supply.

These considerations show,—first, that the human mind is the highest created thing of which we have any knowledge, its conceptions of what is greatest in the highest degree must be founded on what it knows to be the greatest and highest in himself; and, secondly, that we have no difficulty in understanding how this image of the Highest, may, and must be, faint—without being at all unreal or untrue.

There are, moreover, as we have seen, some remarkable features connected with our consciousness of limitation pointing to the conclusion that we have faculties enabling us to recognize certain truths when they are presented to us, which we could never have discovered for ourselves. The sense of mystery which is sometimes so oppressive to us, and which is never more oppressive than when we try to fathom and understand some of the commonest questions affecting our own life and nature, suggests and confirms this representation of the facts. For this sense of oppression can only arise from some organs of mental vision watching for a light which they have been formed to see, but from which our own investigations cannot lift the veil. If that veil is to be lifted at all, the evidence is that it must be lifted for us. Physical science does not even tend to solve any one of the ultimate questions which it concerns us most to know, and which it interests us most to ask. It is according to the analogy and course of Nature that to these questions there should be some answering voice, and that it should tell us things such as we are able in some measure to understand. Nor ought it to be a thing incredible to us —or even difficult to believe—that the system disclosed should be in a sense anthropomorphic—that is to say, that it should bear some very near relation to our own forms of thought—to our own faculties of mind, and soul, and spirit. For all we do know, and all the processes of thought by which knowledge is acquired, involve and imply the truth that our mind is indeed made in some real sense in the image of the Creator, although intellectually its powers are very limited, and morally its condition is very low.

In this last element of consciousness, however—not the limitation of our intellectual powers, but the unworthiness of our moral character—we come upon a fact differing from any other which we have hitherto considered. It is not so easy to assign to it any consistent place in the unities of Nature. What it is and what it appears to indicate, must form the subject of another chapter.

PROGRESS OF BOTANICAL SCIENCE IN THE UNITED STATES.

By J. C. Arthur.

The sketch by Professor Bessey in the December *Naturalist* of the work in Botany done in this country during 1879 is very interesting, and offers an opportunity of comparing the present status of the Science in America with its progress elsewhere. The article shows which departments have been most cultivated, and indicates to some extent the thoroughness and value of the observations and researches. The principal activity was manifested in Descriptive and Systematic Botany, and that largely among Phanerogams and Ferns. Such examples as Mr. Watson's "Revision of North American Liliaceæ" and Dr. Gray's "Botanical Contributions" are of the highest scientific value. These are accompanied by others which are little, if at all, inferior. Large and elegant works like Eaton's "Ferns of North America," Meehan's "Native Flowers and Ferns of the United States," Goodale's "Wild Flowers of America,"

and Williamson's "Fern Etchings," are signs of the healthy growth of popular interest in the objects of the Science.

Among the lower orders of plants, systematic work has not been so vigorous. The literature is widely scattered, and of many of the groups is in a most dishearteningly chaotic state. The disentangling and critical arrangement of this matter is at present one of the most important services that could be rendered the student. The labor of consulting all the descriptions belonging to any one group is often very great, and is always accompanied with a doubt if complete success has been attained. Further perplexities are the unequal value of the material when found, and the difficulty of determining synonymy. Monographs of the groups are exceedingly desirable; but such exhaustive studies are not often made, and in lieu of them careful compilations, aided by as much investigation and verification as possible, are very useful. Professor Bessey's "Erysiphei," Mr. Peck's "United States Species of Lycoperdon," and Dr. Halsted's "American Species of Characeæ" are admirable examples of such contributions to the advancement of knowledge.

It is a law in the growth of a biological science that the objects with which it deals must be carefully identified and systematically described before much progress will be made in the recondite investigations of structure and development, and the relations to physical forces, or in the higher problems regarding the *rationale* of forms and processes. Every advancement in morphology and physiology, however, reacts upon classification and helps to establish it upon a more satisfactory basis. While systematic work is thus the very foundation of the science, it is only by following it up in the same zealous manner with anatomical and physiological researches that the science makes most substantial advancement.

It is manifestly the natural and wise thing for American botanists to collect herbaria and study floras till the species and their distribution are fairly known. For Phanerogams and Ferns this has been well accomplished, and approximately so for Mosses and Liverworts, but the Thalloyhytes (Algæ and Fungi) remain comparatively unknown. Not but what there is still room for excellent systematic work among Phanerogams, but that the stumps and stones and other obstacles in the field have been pretty fully cleared away and it is now a matter of plain cultivation, while the other departments of the science need earnest workers who are not afraid of difficulties, and are willing to clear up and cultivate single handed as large areas as possible.

In the article cited, the Professor feels called upon to apologize for the neglect of Anatomy and Physiology during 1879. He says:—"While we may regret that so much of the field has been so sadly neglected in our country, we should remember that, as a rule, our botanists are overloaded with other duties which render it often impossible for them to command the time for making the necessary investigation." Admitting that the plea partly accounts for the inactivity, it still does not seem to touch the chief cause of the difficulty. It is rather to be ascribed to a lack of enthusiasm for these subjects. They have not yet come into vogue with lovers of the science: the tidal wave of laboratory and experimental Botany is yet but slightly felt; the problems seem new and strange, and just where and how to attack them appears obscure and uncertain. The work already done in these fields has mainly related to the means and accompanying phenomena of the fertilization of flowers. Some excellent papers have been published, although not lengthy. Histology, Embryology, and Physiology proper, however, appear almost without followers, judging from the results communicated. At the present time, Germany is the centre of the most active researches relating to the latter subjects, and France is not far behind.

In order to keep informed of the latest discoveries and results in the botanical world, an acquaintance with the journals in which they are announced is imperative. It is a trite saying in matters of daily life, that if one wishes to be "posted" he must read the papers. This applies even more forcibly to botanists, because their usual isolation deprives them of most other means of obtaining botanical news.

Among the most important exclusively botanical journals are the following: *Botanisches Centralblatt*, abstracts of the latest writings, and a full index, for all departments of the science; *Botanische Zeitung*, anatomy and physiology chiefly; *Flora*, general botany; *Pringsheim's Jahrbücker.*, physiological botany; *Hedwigia*, cryptogams; *Annales des Sciences Naturelles Botanique*, general botany, but with a large share of anatomy and physiology; *Bulletin de la Société Botanique de France*, general botany; *Journal of Botany*, largely systematic; *Grevillea*, cryptogams; and the two home journals—*Bulletin of the Torrey Club*, largely systematic; and *Botanical Gazette*, general botany, but inclined towards physiology. The first two of the list are weeklies; *Flora* is issued in thirty-seven numbers, and the others are monthlies. Beside these there are a large number of periodicals which devote considerable space to botanical matters, such as the *Quarterly Journal of Microscopical Science, Hardwicke's Science Gossip, American Naturalist, American Monthly Microscopical Journal*, etc. If one were confined to two, probably the *Botanische Zeitung* and the *Bulletin de la Société Botanique*, would prove the most satisfactory, presuming that the home journals are also taken, as a matter of course. Mr. Douglas, of Richland, N. Y., proposes to issue a translation of the *Zeitung*, for less than the subscription price of the original (but without the plates, we suppose). This laudable undertaking should receive substantial encouragement from English speaking botanists.

Probably there is no better indication of the beginning of a new era for American botany, than the changes made in the recent text-books. Dr. Gray's "Botanical Text-book" is expanded into four volumes, treating of the Morphological Structure of Phanerogams, Histology and Physiology, Cryptogams, and the natural orders of Phanerogams, respectively. The second volume is to be written by Dr. Goodale, and the third by Dr. Farlow. The first volume of the series has already appeared.

THE DETECTION OF STARCH AND DEXTRIN.

By Spencer Umfreville Pickering, B. A., Oxon.

In conducting some experiments in which it was necessary to ascertain the presence or absence of starch in a liquid containing various amounts of dextrin, the few facts here described were brought to light, and may, perhaps, be of sufficient interest to warrant their publication.

When a solution of starch which has been colored blue by the addition of iodine is heated, it is found that the temperature at which the color disappears varies with the intensity which it possessed before heating. Thus, for instance, 100 c. c. of a rather dark iodine-starch solution on being heated gradually in a flask became perfectly colorless at 58° C., and, on being cooled, showed a slight reappearance of color at 49° C., whereas an opaque blue solution did not lose its color till heated to 99° C., and became visibly colored again when cooled to 63° C. Similarly variable results were obtained by experimenting on iodine-starch solutions in sealed tubes, the temperatures of reappearance being much more constant (generally about 50° C) than those of disappearance; this no doubt is due to the fact that, the stronger solutions having been heated to a higher temperature than

the weaker ones in order to effect the disappearance, a greater quantity of the iodine present in them would have been converted into hydriodic acid, and this would tend to an equalization of the amounts of iodine present on cooling in the various cases. Owing to this conversion of iodine into hydriodic acid, the solutions on cooling, as might be expected, are considerably lighter than they were before heating, and their intensity naturally depends to a great extent on the rapidity with which they have been cooled; even a very weak iodine-starch solution which has been heated may be made to re-assume its color if cooled very quickly.

The amount of starch which may be recognized by means of the iodine reaction varies, of course, with the bulk of liquid operated upon. Using about 200 c.c. the weakest solution which gives an easily discernable blue tint in a beaker contains about 0.0001 per cent. of starch, while if small quantities are examined in a test-tube this percentage must be doubled in order that the color may be rendered visible. The green color which is noticed when a large quantity of iodine is added to a weak solution of starch, appears to be due simply to the combination of the proper yellow color of the free iodine with the blue color of the iodine-starch.

When two weak solutions of iodine, to one of which some starch has been added, are exposed to the air in an uncovered beaker, the iodine in both cases disappears entirely in the course of a few days, but more slowly from the solution which contains the starch; hence the iodine which disappears (owing partially to its volatilization into the air and partially to its hydrogenation) seems to be retained to a certain extent by the presence of starch. The presence of iodine has a reciprocal action in the preservation of starch. A solution of starch, which, in a few days, is converted into dextrin, may be preserved unaltered for a long time—possibly for an indefinite time, if an excess of iodine is present in it.

When a sufficient quantity of iodine is added to a solution of dextrin, a deep brown color is produced; the colored compound which is here present is in a state of true solution, whereas in the case of starch it will, as is well known, settle entirely to the bottom of the liquid in deep blue flocks, leaving the supernatant solution quite colorless, and these flocks on agitation are disseminated again so as to form an apparent solution. The dextrin reaction with iodine is not nearly so delicate as that of starch; the weakest solution which gave any discernable color on being tested contained 0.005 per cent. of dextrin, and in this case the color could only be detected by using about 200 c.c. of the solution, and comparing the color with that of some iodine solution of the same strength as that to which the dextrin had been added.

With starch, the first drop of iodine which is added produces a permanent coloration. With dextrin, however, this is not the case; the color produced by the first drops disappears instantly and entirely. A considerable quantity must be added before a moderately permanent color is produced, and the reaction, owing to which the iodine disappears in this way, will continue for six or seven days. Whether the dextrin disappears or not at the same time has not been ascertained, although it seems most probable that it should do so.

When a solution of iodine-dextrin is heated, the color becomes lighter and gradually disappears, as in the case of iodine-starch, but the temperature at which this disappearance takes place is considerably lower. An opaque brown solution on being heated in a flask became colorless at about 81° C., and, on cooling, regained its color with considerable diminution in intensity) at 64° C. A solution of one-quarter the strength of the preceding one lost its color at 52°, and regained it on cooling at 34° C.; here also, as in the case of iodine-starch, we find that the colored principle does not become colorless at any particular temperature, but its disappearance is dependent on its original intensity.

The dextrin usually met with in commerce contains a considerable amount of starch, which, however, may be entirely converted into dextrin by prolonged heating at 140° to 160° C for several hours, after which it gives the pure brown reaction with iodine above mentioned.

When iodine is added in excess to a mixture of starch and dextrin, the colors produced are blue, violet, purple, claret, red-brown, or brown, according to the various proportions in which the two substances are present. When the iodine is added gradually to the mixed solutions the colors produced, both temporary and permanent, follow the same order as those above mentioned, the blue colors appearing first, and the red ones only on the addition of larger amounts of iodine. Conversely, when the colored solution is allowed to stand, the red tints disappear first, and the blue ones last. Obviously, therefore, the gradual addition of iodine affords an easy and delicate means of detecting starch in the presence of even a large amount of dextrin. Another way in which starch may be detected in similar cases, is to add an ample sufficiency of iodine to produce a permanent color, and then to heat the liquid; the brown iodine-dextrin is decomposed at a comparatively low temperature, while the blue iodine-starch remains till the heat is raised considerably higher, and again, on cooling, the blue tint reappears long before the brown or red tint does; even when there is not sufficient starch to yield satisfactory results by this method, it may often be detected by the liquid being of a more bluish tint after the heating than it was before it.

O. Knab (*Chem. Centr. Blatt*, 1872, 492) found that some dextrin which he had prepared by repeated (ten times) precipitation with alcohol gave the reaction of a mixture of dextrin and starch, and hence concluded that it still contained some of this latter substance. It appears superfluous, however, to raise an impure preparation to the dignity of a chemical compound by giving it a distinct name—dextrin-starch—as Knab does. On leaving a mixture of solutions of starch and dextrin for some days, Knab found that, whereas the addition of iodine had at first caused a deep blue coloration, after a time nothing but the red or brown color of iodine-dextrin was produced, and hence draws the somewhat startling conclusion that starch under the influence of dextrin is converted into dextrin. A simpler and more probable conclusion from these experiments would surely have been, that at the end of the few days during which his experiments lasted, the starch had suffered that spontaneous decomposition to which it is, as is well known, so prone, leaving in solution nothing which would give a coloration with iodine but the unaltered dextrin.

Dextrin and starch, it appears, give entirely different reactions with iodine; the former combines with the halogen to form a brown soluble substance, whereas the latter forms with it a deep blue insoluble body; and these two reactions are so distinct that presence of either of the reagents may be easily detected in a solution containing both of them.

The fact that the addition of iodine to dextrin produces only a transitory color at first, and that an excess of it is necessary to give a permanent tint, will, no doubt, explain the various discordant statements which exist as to whether any color is produced by the mixture of these two substances or not, and will probably render unnecessary the theory of there being two or three different dextrins, as proposed by Mulder and Griessmayer.

DETERMINATION OF THE FATAL DOSE OF CARBONIC OXIDE FOR VARIOUS ANIMALS.—Air containing 1-300th of its volume of carbonic oxide proved fatal to a dog when inhaled for fifty minutes. In another dog of the same size the fatal dose was 1-250th. A rabbit resisted various proportions up to 1-60th. A sparrow perished with 1-500th.—M. GREHANT.

MICROSCOPY.

The annual reception of the New York Microscopical Society will be held on Monday evening, February 14th, 1881, at the rooms of the New York Academy of Sciences, No. 12 West 31st street.

Microscopical preparations of great interest will be exhibited, and the Board of Managers extend a cordial invitation to all possessing microscopes to attend the meeting. We trust that those microscopists residing in the city, who are not members, will avail themselves of this opportunity to observe the many facilties this society offers for extending a knowledge of this branch of science. Microscopical Societies do not profess to teach, but students will find ample opportunities of having the best methods of preparation practically explained to them, and by associating with the members at the ordinary meetings, information on any point relating to microscopy can be readily obtained. The annual dues of this society amount to $5 a year. Cards of admission to the *soirée* can be obtained of Professor Hitchcock, 53 Maiden Lane, New York City.

ASTRONOMY.

DR. B. A. Gould, Director of the Cordoba Observatory, Argentine Republic, has been unanimously elected a corresponding member of the Paris Academy of Sciences in the section of Astronomy, to fill the place of the late Dr. Peters.

The Observatory of Dunecht, near Aberdeen, Scotland, has undertaken the important matter of informing the astronomical observers in the United Kingdom, by means of circulars through the mails, of such facts as must be immediately made known to be of use. It has already issued thirteen circulars, and promises to be of the greatest advantage to British Astronomers.

W. C. W.

REMARKABLE METEOR.

Whilst returning home on the evening of December 29, 1880, I observed a very brilliant and somewhat remarkable meteor. Having seen no observation of this meteor published, and as it may be of interest, I will give a description.

The night was just beginning to be dark enough for the principal stars to shine brightly, the sky being intensely clear, with a cold, cutting wind from the west, the thermometer being below zero. My attention was suddenly attracted by a brilliant light; looking hastily up, I observed the meteor. It was very white and brilliant, with a short train; there was no sensible disk. It started from near δ *Aquarii* and moved at a moderate speed, passing some four or five degrees south of Venus, and appearing fully twice as large as that planet. After passing Venus a short distance, it suddenly flared up as if an explosion had occurred. It immediately slackened its speed, and assuming the brilliancy of a dullish first magnitude star, it floated slowly down in a slanting direction toward the southwest horizon. I watched closely, expecting to see it sink behind the horizon. It sunk slower and slower until, at an elevation of not more than 2°, it disappeared suddenly.

From the moment of explosion until its disappearance it was the size of a dull yellowish first to second magnitude star. No explosion was heard. It was first seen at about R.A. 22h. 54m. south declination, about 15°, disappearing at about R.A. 19h. 44m. and 19° or 20° south declination. Its visible path was about 42°.

It remained visible for fully half a minute, the greater portion of the time being after the explosion. Time, 6 hours Nashville m. t. Did any other observer note this object?

E. E. BARNARD.

NASHVILLE, TENN., *January* 19, 1881.

JUPITER.

THE RAPIDLY MOVING WHITE SPOT.

The white spot, described by me in "SCIENCE" (No. 24), having continued permanent up to the last observation of Jupiter, led me to investigate its history. Tracing backward through my note-book, I find observations at intervals of the same spot, the first observation being on June 26, 1880.

On account of its rapid motion and frequent variation of form I had at each observation failed to recognize the identity of the objects seen.

The spot has invariably borne the same relative position to a long sinuous rift in the northern part of the equatorial band. In 1879 a similar spot was observed, bearing then the same relative position to a similar rift. It is probable that the object seen in 1879 is identical with the present white spot.

My observations this year show a decided variation in the rotation period of this object. Its varying velocity is doubtless due to changes in its form. My sketches show it to be at times scarcely noticeable as a pale, tolerably well defined spot. At other times it is shown as a long curved brilliant spot with its head "tucked" under towards the south, apparently plowing the dusky material of the equatorial belt before it, and a well-defined luminous train following in its wake. A sufficient number of observations have not yet been obtained to decide under what form it attains its greatest velocity. It is likely some sort of violent action takes place in the spot, under the influence of which it becomes very white, increases its motion throwing off a luminous train and cleaving the matter composing the great equatorial "river" like a vessel scudding before the gale. The action in the spot then gradually becomes quiescent, its motion slackens and it drifts along shorn of its train and scarcely recognizable; remaining thus until the forces in it are again at work, when it will once more pursue its rapid course in all the glory of a streaming train. But a lack of observations leaves its times of greatest motion in doubt, and it may be that the motion is greater when its appearance is less conspicuous.

On December 31 this object was seen as a pale, well-defined spot without any train. It was slightly following —by about two or three minutes—the meridian of the following end of the great red spot, having, since the middle of November, made a complete circuit of the planet, and was once more passing the red spot.

At the next observation, January 7, it had left the red spot a considerable distance behind, coming to the middle of the disk one hour before the red spot was central, having passed that object at about the time predicted in "SCIENCE" (No. 24.)

From the observations of June 26, 1880, and January 7, 1881, I get a rotation period of 9h. 50m. 47s.; in this case the transit on June 26 was estimated from a sketch The observations of Nov. 22 and December 2 give a period of 9h. 50m. 19s. Transits of November 22 and December 29, give a period of 9h. 50m. 14s. Transits of November 22 and January 7 give 9h. 50m. 5s. An estimated transit on August 17 and observed transit of January 7 give for its rotation 9h. 50m. 9s. It makes a complete circuit of Jupiter, compared with the red spot, once in 45.08 days. If at any time it is seen passing the red spot it will in forty-five days go completely around the planet and back to the red object again, which would indicate a daily velocity of 6170 miles, or 257 miles an hour.

DETECTION OF ALCOHOL IN ETHEREAL OILS.—A. Drechsler employs, as reagent, a solution of 1 part potassium bichromate in 10 parts nitric acid of sp. gr. 1.30. Alcohol, if present, is at once betrayed by the pungent odor of ethyl nitrite.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

RELIEF TO THE JEANNETTE.

To the Editor of "SCIENCE:"

In compliance with your request concerning my views of the present probable status of the *Jeannette*, and especially the subject of a relief party to be sent to her, I would state that not desiring to renew at length the reasons set forth in the New York *Herald*, of January 12th, I will confine myself mainly to the few but important motives which point to the necessity of such a step in so far as they concern the interest of science. The urgency of immediate succor has been so thoroughly dwelt upon by yourself and others interested, that it can receive but little addition at my hands; suffice to say that the greater majority of Arctic accidents to naval expeditions, which would demand assistance, are of a violent character, such as wreck, ice-pressure, besettal and abandonment, etc., and which show plainly that rescue here, like that in all other zones, must be immediate to be effective in such emergencies. Also the necessity of replenishing the weakened portion of DeLong's crew, should they have been unfortunate in securing a sufficient supply of fresh meat can not be too strongly presented, for such a circumstance might fatally compromise an otherwise successful termination of the voyage, and just at the critical period of the undertaking. In a scientific point of view the field entered by the *Jeannette*, and which would be entered by her relief ship (which should carry a full and complete scientific corps) is one of the most interesting character. Nearly all of the Arctic estuaries of the Atlantic, have been more or less covered by the scientist and their fields of geography, physical and otherwise, their geology and minerology, their fauna and flora and many other kindred and interesting sciences, form huge volumes in the many libraries accessible to the student of these various topics, but on the Pacific side the many branches of science there presented form a vast field of investigation and research almost yet untrodden. That Lieutenant De Long's expedition could circumscribe, even in outline, this great theatre of undeveloped scientific resources is clearly impossible, and there have been but few predecessors along his route to show anything of value to those most deeply interested.

Every civilized nation has taken a public pride in bringing to light all the scientific knowledge attainable, pertaining to its own domain and its adjacent waters, acknowledging defeat and chagrin where it has been left to those differing in blood and allegiance to accomplish. It is only the savage, the barbarian, and semi-civilized community, that can allow these peaceful invasions without patriotic mortification or national chagrin. The Pacific Polar Seas are adjacent to the colonies of our own country and those of Russia. The latter has no great seaports or readily available fitting points in her Pacific coast whence an expedition may sail. With us, on the contrary, our Occidental shores are studded with goodly sized cities, one of which for such a purpose is as perfect as any in the world. It is therefore the plain duty of America to harvest this field, at least, even if the grain must be sent abroad to be ground.

It has also been proposed to establish permanent stations in the Arctic for scientific purposes, all nations uniting, forming a grand international chain, whose united observations will settle many disputed, and probably bring forth and illustrate many new, theories in the science of these zones, especially in the domain of meteorology, where continuous observations are so essential. To cover the Alaskan coast would be the least that could be expected of us, and it is not at all doubtful but that the British American shores belonging more peculiarly to us, by reason of contiguity, than to Great Britain, by reason of colonial possession, would be partially assigned to us, at least in this scheme. The relief party sent to the *Jeanette* could found this little colony, herself make extended investigations, and subserve the purpose of humanity by rescuing or relieving an expedition of our own countrymen under our own flag.

In all cases of abandonment of vessels in Arctic waters, the scientific collections have necessarily been left, as nothing should burden the retreating crews, except absolute necessaries, in a race for life where every ounce of weight is of vital importance, and these collections are almost as good as lost when only feebly represented by their descriptions and imperfect sketches. Such has been the fate of so many collections, rendering the voyage, in a scientific sense, almost *nil*, so that the rescue of an expedition, with such facilities of research, should meet the hearty encouragement of every scientist of America.

F. SCHWATKA.

GOVERNOR'S ISLAND, NEW YORK HARBOR,
January 29, 1881.

HYPNOTISM.

To the Editor of "SCIENCE:"

I doubt not that many of the readers of "SCIENCE" who attended the recent lecture of Dr. Beard, before the New York Academy of Sciences, will be surprised to read the article which you have published on page 13, Vol. II. It is not my purpose in this letter to defend the position of Dr. Beard in this matter, for if he deems it necessary I have no doubt he will give a satisfactory explanation of the few minor points which have given rise to your suspicions as to the genuineness of the phenomena. The circumstance of the person who was rendered deaf, and who was roused from his trance in the surprising manner which you describe, likewise aroused some questions in my own mind, as did also one or two other experiments; but instead of selecting these as a basis for adverse criticism, it has seemed to me more in accord with scientific methods to first inquire what explanation of them Dr. Beard himself can give.

The question before the general scientific world is not whether we can pick out single points for criticism, but whether the phenomena, as a whole, are genuine. The study of trance is not one with which most of us can claim familiarity, and although it is one which, more than almost any other, demands very special training to enable a person to profitably investigate the phenomena, we seldom find a person, even among scientific men, who has not his own ideas or theories or explanations about it. For this reason, Dr. Beard's careful study of the subject probably will not be fully appreciated during this, in some respects, conservative generation. Physical phenomena may be tested and abstruse hypotheses framed to explain them, and the world will accept the explanation; but in matters of trance, the clearest demonstrations cannot shake deep-seated beliefs, or convince unreasoning skeptics.

What has been the attitude of scientific men in the past toward this subject? It has been one of disbelief and nothing more. It is true that many of the phenomena (not all of them) have been known for many years. Your statement, however, that "nearly all our present knowledge of the subject dates from Braid's book" was directly contradicted by Dr. Beard in his lecture. Your assertion is only true of the phenomena. Dr. Beard's object was not to give an amusing exhibition of the phenomena of trance before a scientific body, but to explain them; the experiments being merely illustrative of the subject. I have still another criticism to make. You have assumed that "two of the subjects were evidently trained performers, if not professional actors." Admitting this

mere supposition, to be true, what possible bearing can it have upon the result? Why should not professional actors be as good subjects as any other persons? This objection seems to me about on an equality with some others which I have heard, *e.g.*, that all the subjects were trained to perform to suit the occasion. Your assertion that "the subjects of Dr. Beard are selected from the nervous classes of our population," is in direct contradiction to the doctor's declaration. In no sense can I regard your criticism as quite fair. Moreover, you have neglected to mention two of the most convincing demonstrations of the reality of the phenomena,—I refer to the extraction of two teeth from one subject, and the application of actual cautery to another. The opinion seems to be very common that the phenomena of mesmeric trance cannot be genuine unless all persons can be brought under its influence. A very little reflection will show that this is an erroneous opinion. There is much more that might be said upon the subject, but my purpose is only to correct the erroneous impressions which I am sure your article will give to many readers. I hope the columns of "SCIENCE" will be held open for a free discussion of these phenomena. R. HITCHCOCK.

To the Editor of "SCIENCE:"

In Dr. Spitzka's suggestive "Notes on the Anatomy of the Encephalon, etc.," in "SCIENCE," No. 29, occurs the following passage:

"Now, the third ventricle, as shown by Hadlich and Wilder, extends over the entire thalami."

I regret to be obliged to make a correction. The passage contains two distinct statements: the one, that the third ventrical extends over the entire thalami, and the other that such was shown to be the case by Hadlich and myself.

Since upon this point—as upon all others presented in the article—no exact references are given, I will not speak now of Hadlich's views; but no such statement has ever been made by me, and I am at a loss to understand how Dr. Spitzka can have gained that impression. On the contrary, my paper "On the Foramina of Monro in the Domestic Cat," read at the Boston meeting of the A. A. A. S., but not yet published, included an expression of my belief that, in the cat, the dorsal limit of the third ventricle on each side corresponds with the *Habena*, (the so-called "peduncle of the pineal body,") along which the *Endyma* (the lining membrane of the ventricles), is reflected from the mesial surface of the thalamus toward the opposite side. Hence, only the mesial aspect of each thalamus is "in the third ventricle," the remaining and much larger part of the surface being wholly extra-ventricular. BURT G. WILDER.

ITHACA, N. Y., *January* 26, 1881.

BOOKS RECEIVED.

BULLETIN No. 3 of the Illinois State Laboratory of Natural History at Normal, Ill., is a pamphlet of 160 pages, containing papers by the Director of the Laboratory, Prof. S. A. Forbes, on the following subjects: On some Interactions of Organisms; The Food of Fishes; Acanthopteri; On the Food of Young Fishes; The Food of Birds; Notes on Insectivorous Coleoptera. Likewise a brief but significant paper—Notes upon the Food of Predaceous Beetles, by Mr. F. M. Webster, who has independently come to the same conclusion as Prof. Forbes that the Carabidæ, in place of being exclusively insectivorous as is generally supposed, can, and in fact do, derive considerable sustenance from grains, grasses, and other vegetable substances.

The instructiveness and practical as well as scientific value of the researches which form the basis of these papers may be inferred from their titles, and from Prof. Forbes' well known accuracy and enthusiasm. But they are also very interesting and entertaining reading, and will thus be more apt to reach the minds of many who would otherwise fail to profit by the stores of information they contain. It would be well for other states to make the slight provision required for carrying on similar investigations into the food habits of the Birds, Fishes and Insects found within their limits.

B. G. W.

CHEMICAL NOTES.

DETECTION OF IODINE IN BORMINE AND METALLIC BROMIDES.—A few drops of the bromine in question are placed in a small porcelain capsule, 30 c.c. of a solution of potassium chlorate, saturated in the cold, are added, and the liquid is boiled till colorless. The solution is then poured into a test-tube, allowed to cool, mixed with a few drops of a solution of morphine sulphate and a little chloroform. If the chloroform takes a violet color, iodine is present in the sample. The morphine solution is prepared by dissolving 0.5 grm. morphine in an excess of dilute sulphuric acid, and diluting to 50 c.c. In examining potassium bromide the solution is mixed with 2 or 3 drops of pure bromine water, and a few c.c. of a cold saturated solution of potassium chlorate, and further treated as above. —A. JORISSEN.

DETERMINATION OF SULPHUR IN IRON PYRITES.—On oxidizing pyrites with nitric acid and precipitating the sulphuric acid from the ferriferous solution, slightly acidified with hydrochloric acid, there is always obtained a barium sulphate, contaminated with iron, and still the results were too low. The following process is, therefore, adopted: 1 grm. pyrites was mixed in a large covered crucible with 8 grms. of a mixture of equal parts potassium chlorate, sodium carbonate, and sodium chloride. The crucible is heated at first gently so as to dry the contents, which are afterwards melted at a high temperature. The mass when cold is treated with boiling water, and the solution together with the deposit is introduced into a measuring-flask of 200 c.c. filled up, filtered, and the sulphuric acid is determined in aliquot parts, say 50 c.c. The insoluble residue does not retain any sulphuric acid. In this manner the use of nitric acid is evaded. The decomposition of the potassium chlorate is complete.—BERNHARD DENTECON.

CONTRIBUTION TO ELECTROLYSIS.—L. Schucht describes the electrolytic determination of uranium, thallium, indium, vanadium, palladium, molybdenum, selenium, and tellurium. For qualitative analysis he uses a strong test-glass, 10 to 12 c.m. high, and 1.5 c.m. wide, fitted with a cork coated with paraffin. Two platinum wires, 1½ m.m. in thickness, pass through the cork down to the bottom, and are connected above the cork with the polar wires of the battery by means of small binding screws. This decomposition tube may be held in a wooden clamp. After the current has passed through the solution to be analyzed for ten to fifteen minutes, the stopper with the wires is drawn out, without interrupting the current, and the deposited metal is determined by its color, lustre, solubility in acids, &c. The manner of decomposition and the slight or strong evolution of gas is noticed. The solution is completely precipitated, rendered alkaline, and again electrolysed, after the wires have been cleansed. Copper is recognised by its color, mercury by the precipitated globules, nickel and cobalt by their lustre and sparing solubility in acids, zinc and cadmium by their color and solubility in potassa. The formation of peroxides is characteristic for lead, silver, bismuth, thallium, manganese. Bismuthic acid is gradually formed, whilst the peroxides of lead, silver, and thallium are deposited at the beginning of the precipitation. Silver peroxide dissolves in ammonia with liberation of nitrogen. The decomposition of the alkalies and alkaline earths is best effected in a U-tube. The hydroxides of the latter are separated in a voluminous form; those of calcium and magnesium in white crusts. The hydroxides of barium, strontium, and the alkalies dissolved on the negative wire, *Berg-und Hütten Zeitung*, 39, 121.

ON MATTER AS A FORM OF ENERGY.

In the vortex-ring theory of matter as propounded by Sir William Thomson, the characteristic differences between the elements is supposed to be due to complications in the rings themselves, as they may be knotted in innumerable ways. Several such forms are drawn in the memoir, and one such is stamped upon the cover of "The Unseen Universe," by Tait and Stewart.

This vortex-ring theory assumes that matter is a *form of energy*, not interchangable with the other variable forms, such as heat, electricity, etc., for the simple reason that its *form* renders it impossible, but if the elements be forms of energy, the law of energy may possibly be traced in them. Now, the energy of a given mass of matter varies as the square of its velocity, but the *properties* of the mass vary with the form of the energy, that is to say, the physical properties of a heated body are not identical with those of the same body when it is cool, but possesses the same amount of energy in free path motion. The physical properties of atoms and molecules vary with atomic and molecular velocities; for example, whether a piece of iron or steel is magnetic or not depends upon its temperature, that is, its rate of molecular vibration. It is not, therefore, *a priori* improbable that such differences as exist between the ultimate atoms constituting what we call *mass*, may be due to relative velocities of rotation of the vortex-ring. Atomic weights represent numerically these constant differences, and one might expect to find in any one of these atomic weights the two factors that constitute energy, namely a mass (or its equivalent) and a velocity; so we might write $\frac{m\,v^2}{2}$ = atomic weight. Applying this to a specific case, suppose $\frac{m\,v^2}{2} = 75$ = atomic weight of Arsenic; by inspection it is seen that $m = 6$ and $v = 5$. If $m = 6$ and $v = 2$, then $\frac{6 \times 2^2}{2} = 12$ = At. Wt. Carbon. Let a table now be constructed $m = 6$ and v with values 2, 3, 4, and so on, and there results a series of numbers N either exactly the same as the atomic weights of some of the elements or a very close approximation to such numbers. The elements have their symbols under E with their atomic weights as given under At. Wt. for comparison.

$\frac{mv^2}{2}$ = Energy=Atomic Weight.

	N.	E.	At.Wt.		N.	E.	At. Wt.
$m=6$				$m=9$	18	?	----
$\frac{6\times 2^2}{2}=$	12	C.	12		40.5	Ca.?	40
$\frac{6\times 3^2}{2}=$	27	Al.	27		72	?	m
	48	Ti.	48		112.5	Cd.	111.6
	75	As.	75		162	?	----
	108	Ag.	108		220	?	----
	147	Di.	147	$m=11$	22	?	----
	192	?	---		49.5	?	----
$m=7$	14	N.	14		88	Sr.	87.2
	31.5	P.?	31		137.5	Ce.	137
	56	Fe.	56			Ba.	136.8
	87.5	Sr.	87.2		183	W.	184
	126	I.	127	$m=12$	24	Mg.	24
	171.5	Er.?	170.6		54	Mn.	54
	224	?	---		96	Mo.	95.8
$m=8$	16	O.	16		125	?	----
	36	Cl.?	35.5	$m=13$	26	?	----
	64	Cu.	63.3		58.5	Ni.	58.6
	100	?	m			Co.	58.6
	144	?	m		104	Ru.	103.5
	196	Au.	196			Rh.	104.2
		Pt.	196.7		162.5	?	----
		In.	196.7		234	Th.	233.9
		Os.	198.6				

By changing the value of m to 7, 8, 9, etc., a new series of numbers is obtained and the process is carried until the resulting number is higher than any known atomic weight, namely, that of Thallium 233.9. Where the number obtained is not that of any known atomic weight an interrogation point is placed. In several cases the resulting number is the same as the ones given by Mendelejeff as those of probable elements yet to be discovered; for example, in table $m = 9$. 72 is such a number and is marked m in the line of atomic weights.

Now, here is a series of forty numbers calculated serially, and thirty-three of them are either the exact atomic weights of elements or vary less than one unit from them, and it does not seem probable that so large a proportion could be the result of chance, for the numbers range from 12 to 234. Moreover, by carrying the process still further many more of the atomic weights are obtained. Thus, with $m = 13$ we have Co. Ni. Ru. Rh. and Th.

$m = 14$, Si. Cu. Cd. and one of Mendelejeff's hypothetical ones.

$m = 15$ only Antimony, 120.

$m = 16$ S. Te. Hg.

$m = 17$ Se. Ce.

$m = 20$ Ca. Zr.

It must be remembered that with this large value for m, only three or four calculations are possible without obtaining numbers quite beyond any known atomic weights; for instance, when $m = 20$, only three calculations can be made, two of which are atomic weights.

With 66 serial computations, 49 elements are determined; 74 per cent. and more than that if Mendelejeff's hypothetical elements may be counted.

If there be any underlying truth in this theory of calculation, then the conception of the elements will be much simplified, for it will dispense at once with complexity in the atom, and substitute a common form for all, differing arithmetically from each other in size and velocity. The only conception I have of the term m corresponding to *mass*, is a relative *volume* of ether in rotation with certain velocity.

TUFTS COLLEGE, MASS. A. E. DOLBEAR.

RECENT ADDITIONS TO THE E. M. MUSEUM AT PRINCETON COLLEGE.

HENRY F. OSBORN, S. D.

The E. M. Museum of Geology at Princeton has recently purchased Messrs. Ward & Howell's well-known collection of fossil animals and plants. Under the partial supervision of these gentlemen the collection has been unpacked and hastily arranged in the cases, and as it has never been fully displayed before, it now appears to very great advantage and possesses peculiar interest. The east wing of the museum already contains the collections made by the Princeton western parties during the summers of 1877 and '78. These include several hundred specimens of fossil insects preserved in the delicate Miocene shales of Florissant, Colorado, and leaves from the same neighborhood. The former have already passed into the hands of Dr. Scudder for identification. Still more valuable is a large collection of fossil leaves from Strata closely overlying the Lower Eocene Lignitic Beds, near Black Butte, Wy. Terr. These have been studied by Dr. Lesquereux; he pronounces them of great novelty as contributing largely to our knowledge of the extent of the Eocene Flora, and they will form the subject of a special memoir to be published by the museum.

Among the western Vertebrate collections are nearly complete skeletons of various members of the Dinocerata family, parts of which have been figured and described in bulletins from the museum. These, together with numerous specimens of *Palæosyops* and allied genera, from the now classical beds of the Henry's Fork and Bitter Creek country, Wy. Terr., together with a great variety of carnivorous, rodent, lemurine and perhaps insectivorous forms, many of which are undescribed, give an admirable idea of the fauna inhabiting the Lower Eocene. In addition to these are many complete turtles and remains of lizards, snakes and birds. Representing the Miocene is a collection from Colorado including widely different forms. Prof. Cope, who has kindly glanced over the whole collection, pencil in hand, pronounces several of these forms new to science.

The Ward collection is, however, of much greater value to the general student, as it includes representative specimens from almost every age and country—from the disputed *Eozoon canadense* of the Laurentian to the Post Pliocene cave bear and Irish elk. It is the result of seventeen years of intelligent travel, purchase and selections. Mr. Ward's theory being to perfect the collection by constantly substituting the best obtainable examples of each type, not aiming at a complete series for each age, but giving a synoptic view from the dawn of life upwards. In this he has succeeded, we have little doubt, far beyond his own expectations at the outset, and although his catalogues have made this collection familiar to many palæontologists in this country, it well deserves a brief description here.

The Silurian corals, crinoids and trilobites fill the first cases. The latter are very fine. Among them is the outline of an *Asaphus gigas* indicating an animal over 12 inches long. On large stone slabs are other Crustacea, *Eurypterus* and *Pterygotus*. These are the earliest of a series represented in the Jurassic by a fine collection from the Solenhofen Beds and throughout by numerous Trilobites. The Solenhofen crustacea include, among others, *Peneus, Glyphea, Eryon, Limulus, Æger,* and a very perfect *Megachirus,* while from the English chalk are some fine fossil crabs, *Enoploclytea, Hoploparia,* etc.

The remains of Devonian Ganoids are very numerous; *Osteolepis, Cheirolepis, Ptericthys, Cephalaspis* and other genera characteristic of the middle and lower Devonian. Most interesting, however, is a fine block containing a number of *Holoptychii* from the old red sandstone, which specimen comes direct from Hugh Millers's collection. From the Lias beds of Lyme Regis are well preserved specimens of *Dapedius, Lepidotus, Eugnathus* and others varying in length from one to three feet. There are fish remains from each epoch. The Solenhofen beds have furnished a very beautiful group, including *Cakuras, Lepidotus, Leptolepis, Aspidorhynchus* and others, imbedded in a clear yellow shale.

There are fine examples of *Lepidodendron* and *Sigillaria* from the English, Prussian and American coal measures; also, many ferns. Among these are perfect remains of *Sphenopteris* and *Pecopteris* from the Scottish coal measures, with a full series from Mazon Creek, Illinois. The fossil flora throughout is numerous, with good collections from the German, Italian and French Tertiary deposits.

From the Jurassic are eleven entire Saurians marked for their exceptional beauty, rather than great size. An *Icthyosaur,* over 11 feet in length, is the largest of a number of skeletons of this genus, and is finely preserved. One complete skeleton and several parts give a very correct idea of *Plesiosaurus.* A head of *Mistriosaurus* complete, rare in this country. From the Wurtemburg Lias is a large *Teleosaur* with the ventral scales in position. There is also a humerus of *Pliosaurus.* Besides these are many fragments; the ossified Sclerotic of Icthyosaurus and parts of the neck, pelvic and shoulder girdles affording a complete study. Probably belonging to the saurians, too, are the so-called bird tracks from the Triassic sandstone of the Connecticut River Valley, including tracks assigned to *Brontozoum, Anisopus* and other genera. Also of the five-toed *Cheirotherium,* supposed to mark the steps of *Labyrinthodon.*

The Echinoderms can be studied almost without interruption. In the earlier crinoid series are *Periechocrinus* and *Pentacrinus* from the older strata. The latter are represented beautifully and in profusion from the Lyme Regis locality, England. Among later forms are *Apiocrinus* and Eucrinus Lilliiformis, a rare specimen from the Brunswick Muschelkalk. In the Echinoid series are perfect specimens of *Periaster, Holaster* and *Hemiaster,* in addition to many others. Beautiful specimens of *Asterias* and *Astropecten* and *Ophiorderma* from the English Lias represent in part the Star Fishes.

The Cephalopods are a great feature of the collection,

beginning with *Endoceras, Gyroceras, Phragmoceras* and others characteristic of the Silurian merging into the more elaborate and coiled *Goniatites, Nautilus* and *Orthoceratites* of the Carboniferous, and into these forms and the *Ammonites* in the Cretaceous. The latter appear in great elegance and profusion from the Lias. In this and the two succeeding ages in which this family reached its maximum the Ammonite and Nautilus group are represented by a number of genera. The series closes in the multiplicity of Cretaceous forms *Ancyloceras, Crioceras, Scaphites, Hamites, Toxoceras* and many others. A heavy slab covered with Trigonia is noticeable among the Lamellibranchs. But a mere enumeration of these series and other Invertebrates that have not been mentioned gives but an inadequate impression of their value as a typical collection, which rests so largely, not upon their number but upon their exceptional perfection and completeness.

From New Zealand are the recent struthious birds, the collection containing many incomplete skeletons of *Meinornis,Dinornis* and *Palapteryx*, and completing the series are three fine Moas, one of them standing 8 feet high. There are important remains of *Halitherium, Titanotherium* and *Rhinoceros*, the latter from the Black Hills. From the Pleistocene shell marl underlying the peat beds near Limerick is a tall Irish elk, *Megaceros Hibernicus*, quite rare in this country. A cave bear from the south of France is one of the most perfect specimens that has been found. It is mounted complete, the ribs and a few vertebræ alone having been restored. These, with a large mastodon from Hudson, N. Y., a skull of Bos Primigenius, and many scattered Mammalian remains give an admirable idea of the Post Pliocene fauna of Europe and America.

The east wing of the museum is almost entirely filled by the collection. It contains no plaster, but the originals of over 130 of Ward's series of casts. It reflects the greatest credit upon the intelligence and energy of its collector. It will come into immediate service in connection with a lately instituted course of lectures upon Palæontology, and give new impetus to the general interest in Biology at Princeton.

THE CLASSIFICATION OF SCIENCE.

Rev. Samuel Fleming, LL. D., Ph. D.

II.

PRINCIPLES OF CLASSIFICATION.

Science may be properly classified with respect to either the order and facts of nature, or the laws of thought and methods of obtaining the knowledge of facts. In respect to the first basis, the classification may proceed upon the twofold method of arranging the order and laws of phenomena, separately considered, or of considering these in their immediate connection. And while either special method involves the complex process of nature, which is the province of philosophy in the discovery of laws,—the object of classification is to set forth the order of facts and laws which have already been discovered. It is a statement of their connections as brought within the scope of observation, as they stand in their completeness of order, while many facts may still remain unknown. Processes are continually going on in the physical realm, as exhibited in the heavens and in the earth. It is hence not a statement of historical development of each particular science, nor of the body of sciences. It is not an arrangement according to the chronological order of discovery of the facts. It is not a curriculum or course of study for discipline and acquisition. Such a course is arranged with reference to a harmonious development of mind, and requires the prosecution of diverse studies pursued simultaneously. Yet a proper classification proceeds upon the method of arranging or grouping the subordinate sciences according to both the order of philosophic inquiry, and of the subordination of facts and principles to the divisions and uses of science from the lower to the higher, and from phenomena to laws and applications.

Further, any scheme of clasification, founded upon material existences and relations irrespective of the immaterial entities which give qualities and motion to the material, must be radically defective. The fact of an order of succession in respect to the modification of the primary Force which inheres in matter, is too obvious to need more than a statement of the fact. Thus, in organic existence, the all-related force of Gravity is *general*, being applied to all bodies, whatever their constituents or mode of combination, while modified forms of this principle are limited to specializations. As at every step in the gradation of material existences, the order of nature is from the inorganic to the organic, so these terms involve the general and the special, and the addition proceeds from the lower and more general forms of force to the higher, more limited and special. Thus, also, in organic being we find Life as a common or general substance or entity, forming the basis of the general division of science denominated Biology. The lowest specialized form of life pertains to Botany,—the science of organic unconscious vegetal life, including many classes; the next higher pertains to Zoology, which is the science of that form of organic life, which has consciousness and animation, including many classes, and subordinate orders, kinds and species. The highest in gradation of being pertains to Anthropology, the science of the form of organic life which is conscious and rational, limited to mankind. In every higher order a new capacity has been added. It has been a "life unto life."

This natural order of classification from generals to specials, and from the lower to the higher, may be illustrated by the following diagrams, commencing with the lower, or gravitation, as in reading the scheme of classification accompanying this paper:

Life, { Man=organization + sensation + rational mind.
Animal=organization + consciousness and sensation.
Plant=organization.

Force, { Special : Chemical affinity.
Special : Cohesion.
General : Gravitation.

The fundamental distinctions of this classification are those which pertain to the body of sciences included in the scheme given. They are first, *Ontology*, the science of being, or the material or immaterial substances, qualities and attributes of universal being. This properly includes not only the general divisions given, but those which relate to the superior orders of being not given, viz.: Angeology, Christology and Theology. A classification of all Science, therefore, embraces these subjects. Ontology includes three general divisions: Cosmology, Biology and Anthropology. These are arranged in their natural order, as based upon the succession of immaterial or spiritual entities united with their respective material forms. Such order is essentially *serial*: in other words, there is a gradation of existences, as just noticed, and as indicated by the branch and group-descriptive terms given in the body of the scheme, as *Physico-dynamic*, etc.

Each general division includes its subordinate divisions or departments. Cosmology, the science of inorganic nature, includes three departments: Physical, Mechanical and Chemical Philosophy. The general term, Dynamology, formed upon the Greek etymon *dunam*, is used to designate the science of the immaterial principle, Force, as Biology designates the science of the vital principle, or Life. Biology and Anthropology include the several branches or departments as given. Individuals of a group are allied by some mode, principle or law distinguishing them from others in special respects.

The progress of science within the past few decades, and the very wide applications rendering divisions of scientific research and use indispensable, has made it necessary more and more to distinguish the several subordinate branches of a general division with reference to special relations and purposes of science. What has been denominated physical science in the reeent past is found to include too extensive a field of culture and use, and to require too vast an amount of scientific labor in research, analysis and application, both for individual gratification and for the demands of science. Then "Natural Philosophy" monopolized the whole field. Now Chemical Philosophy has taken the rank of a distinct department, and has extended its domain in every direction wherever it could find a field of research. It has even been obliged to review its own analyses, and to criticise its own results, by further experiment upon its own elements, to determine whether they are themselves compounds. And the analyses have yielded important fruits. Recently four new elements—cæsium, rubidium, thallium and iridium--have been detected by the new and wonderful method of the Spectrum Analysis, a notice of which will be given farther onward.

But Mechanical philosophy has an equal claim to distinction as a special department. Its aims and uses are practical—the relations and applications of matter and motion to mechanical effects; and in this age of inventive genius and of vastly extended applications of mechanical force to the demands of utility, give increasing importance to this department of science. The distinguishing triumphs of the past few years have resulted from the conservation of those forces and agencies which appear phenomenally in their general relations in physical nature, but are now specialized in this department for the higher uses of human society. Thus the form of force which has operated naturally as heat in all the previous history of matter, has become a science in mechanical philosophy, manipulated and controlled by scientific art, and takes the name of Thermotics, a science of vast extent and application. Hydrology has become specialized in Hydro-dynamics, Aerology in Pneumatics, Electricity in Electro-magnetism, etc. The subdivision of Physico-dynamic science into three departments—Physics, Mechanics and Chemics—seems to be demanded by the vastly extended range and special applications of these, as well as by the legitimate distinction recognized between *phenomena* and *laws*.

Cosmogony is treated as a branch of Astronomy. It is obvious this is its place, from the fact that Stellar Astronomy grows out of it, and includes its forming masses and nebular states. This contemplates a prior state, and the processes of the formation of special masses from the original mass of nebulous matter. The advancement from nebulous masses to globes in the various stages of condensation gives Stellar Astronomy. The sun is one of the stars, and is specialized as the center of the system to which our planet belongs, and hence Solar Astronomy is a consequent, and its place above Stellar Astronomy is appropriate. Again; our earth, far back in the periods of world-formations, was in its cosmogenic stage, forming part of the great nebulous cosmos; hence the term *geogony*, the science of the genesis of the earth, is grouped with *cosmogony*. But while the greater part of the earth's interior is still in its gaseous state, the facts pertaining to its crust create a new sub-group, as Geology, Mineralogy and Seismology.

Biology is divided into two general departments, while it includes three sub-sciences, viz.: Botany or Phytology, Zoology and Anthroposophy,—the latter being the science of the human physiological constitution. The radical distinction between animals and man pertains chiefly to the immaterial nature—the latter possessing rational and moral capacities, and also an order of physical nature not possessed by animals; yet a real distinction obtains physiologically, and indeed a vastly greater difference than between any of the different orders of animals. This distinction is stated in the classification. Physiology, which pertains to man's physical nature, is the sub-science of Biology, termed Anthroposophy, while comparative physiology, and morphology, belong respectively to Zoology and Phytology—the former relating to beings having sentient but irrational life, and the latter to insentient or unconscious life.

If this method of division, in which Biology and Anthropology share in the inclusion of a special subject appears to be anomalous, it is legitimate; for while both include those sciences which are grouped as belonging to physiological nature, Anthropology includes also the higher order of psychical nature, in essential connection with our mental, rational and moral nature,—entities and attributes of an imperishable subsistence, but whose functions and development for temporal existence depend upon the physiological connection. Biology is the general science of organic being having *Life;* Botany is the special science of organic being having *vegetal life;* Zoology is the special science of organic being having *sentient* life; Anthroposophy is the special science of organic being having *rational* life—the latter term having been chosen to express the distinction maintained above. If it is held by any readers of this paper that animals possess a psychical nature, as well as man, be it so. At least a nervo-ethereal nature may be predicated of beings having sensation and the power of voluntary motion; and such a substratum or basis of the physical as well as the sentient nature of animals, as corresponds with man's psychical nature, may exist, perhaps must. If so, it is reasonable to presume it must be of an order as much lower than man's psychical nature, as the mental or sentient constitution of animals is lower than man's. But if such psychical nature does exist, the fact can be known only by rational induction, for the beast has no capacity for language to verify the assumption.

INCOMPLETE, SUBORDINATE AND CONDITIONING SCIENCES.

Few of the physical sciences, especially, can be completly developed by themselves. Physics, Mechanics and Chemics are more or less mutually related, either as conditioned or conditioning. Astronomy has necessarily required for observation of its facts some of the principles and laws of physical optics, while scientific art has been called to construct appropriate instruments for observation, as the telescope and spectroscope. And the laws of planetary and stellar motion must necessarily be known before the science of astronomy can be fully acquired. But classification cannot await the discovery of all the facts of science, but must proceed with the materials at hand, when radical distinctions have been determined.

Geogony treats of general phenomena, the unformed, but forming and mingling elements, and conditions of meteorology by furnishing the materials involved in the latter science, in its special sphere.

Meteorology cannot be completed as a science by the study of the atmosphere alone, but in connection with the facts which reveal themselves by the action of atmospheric electricity. Thermotics, the science of heat, is but partially developed by the study of the ethereal radiations giving the physical phenomena of heat, but finds its completion in the experiments and application of mechanics, of hydrology and pneumatics.

Paleontology, being allied with mineralogy in respect to the general process of stratification, by furnishing materials which enter into it, properly belongs where it is assigned; yet these materials, constituted in part of fossils, cannot be completed without employing the facts which are brought forward in vital organisms. Hence paleontology is given as a conditioning science, contributing to botany and zoology, inasmuch as the ancient organisms, while many of them contain extinct types, are made a study in connection with living organisms;

and thus the apparent anomaly of the same branch of science being grouped both with physics and biology, is explained by the fact that paleontology, in its mere physical relations, deals with substances irrespective of relations to organisms, while fossilogy belongs to both. So, as already noticed, anthroposophy belongs both to biology and anthropology.

Light and sound are grouped together because produced by vibratory motion, yet not affiliated, because the media of vibration differ, the former being ether and the latter air. The analogy between light and sound is illustrated by firing a cannon at a distance from the observer; first the flash of light is seen at the moment of the explosion of the powder, transmitted at the rate of about 184,000 miles per second, the sound being heard some moments after the flash is seen, transmitted at the rate of about 1100 feet per second. Neither the luminous body nor the sonorous body throws off any *substance*, but only gives an impulse in wave-form causing vibrations of different kinds of substance,—ethereal vibrations exciting the optic nerve causing the sensation of seeing, and aerial vibrations exciting the auditory nerves causing the sensation of hearing. But while acoustics (or photology) is grouped with physical optics, in respect to the cause of their production, both musical sounds and colors are grouped as belonging to esthetics high in the series of science. In these respects both phonology and photology are subordinate sciences.

Actinism, produced by vibration of ether, like light, but exceeding in rate those which produce the highest color, *i. e.*, exceeding 800 billions of miles per second, is affiliated with electricity, light and heat, and bears relations to two diverse and widely separated sciences—photography and phytology. Its action is both chemical and vital, operating on the sensitive silver in photography (which more properly may be termed actinography), and also constitutes the vital agency necessary to excite germination in plants. This latter result has been attributed to the violet ray revealed by the spectrum, but this may be owing to the fact that the higher, inconceivably rapid vibrations of ether producing the actinic rays are not appreciated, and the effects in germination have been associated with the highest rays of light brought within the scope of vision. Actinism is hence grouped generally with sound, and specially with heat, light and electricity, but is subordinate to botany. There are reasons for the theory that electricity is concerned in normal vital action—not only vegetal, but animal.

Nature has anticipated both the mechanic and the fine arts. Far down in the depths of mineralogy are found gems of rarest beauty—the esthetics of Architecture. Up in the field of meteorology the clouds are tinted by the sunbeams with a perfection of beauty surpassing the possibilities of the esthetic art of Painting. "The music of the spheres" have for centuries enchanted the votaries of astronomical science, and still challenges the admiration of all observers contemplating the perfection of that grand choral movement which excels the harmony of a Handel or Beethoven—anticipating the rhythm both of Poetry and Music. Mineralogy, meteorology and astronomy belong to physical science, but they have furnished elements of the esthetic forms which reason appropriates in the sphere and achievements of the Fine Arts.

THE ROTATORY POWER OF COMMERCIAL GLUCOSE.*

A METHOD OF DETERMINING THE PERCENTAGE OF REDUCING MATTER BY THE POLARISCOPE.

By H. W. Wiley, Lafayette, Ind.

In the "trade" the name "grape sugar" is applied only to the solid product obtained from starch.

The name "glucose" is given to the thick syrup obtained from the starch, and which is used in immense quantities in this country for table use and other purposes.

Before being sent into the market it is usually mixed with a little cane sugar syrup to give it color rather than flavor, since the glucose itself is quite or nearly colorless. My polariscope is the *holb-schotten* variety, and is used with the sodium monochromatic light. The sugar scale is graduated to give 100 divisions, with a tube 200 m.m. long filled with sugar solution of 26.048 grammes in 100 c.c.

The angular rotation produced is 34°.7, which shows a specific rotatory power of 66°.6 for pure cane sugar.

In all my examinations I took 10 grammes of glucose in 100 c.c., and used tubes of observation 200 m.m. in length.

The average specific gravity of the various glucoses I examined was 1.412, and the number may be taken as a standard.

In order to conform to the following formulæ the specific gravity should not vary greatly from this number.

I have found from a large number of observations that the average reading on the sugar scale for 10 grammes of glucose in 100 c.c. is about 50 divisions. When the reading approached 53 divisions I found that the glucose contained nearly 53 per cent. of reducing matter, as determined by Fehling's solution. When the reading fell below 53 the percentage of reducing matter was above 53 and *vice versa*. I therefore made a large number of observations to determine, if possible, any relation between the polariscopic reading and the percentage of reducing matter.

I found as a result that the difference between the polariscopic reading and 53 multiplied by 1.25 gave a product which, added to or subtracted from 53, would give the percentage of reducing matter required. When we consider the difficulty of hitting the exact point in using the copper solution, the differences exhibited in the following table will not seem so important. See following page.

From a study of the following table we may write the following formulæ:

Let g = percentage of reducing substance, and a = reading of polariscope.

We may have three cases:

1st. $a = 53$.
2d. $a > 53$.
3d. $a < 53$.

For case 1st, $g = 53$ per cent.
Case 2d, $g = 53 - (a - 53)\ 1.25$ per cent.
Case 3d, $g = 53 + (53 - a)\ 1.25$ per cent.

ILLUSTRATIONS.

No. 14, following table.

$a = 40$.
$g = 53 + (53 - 40)\ 1.25 = 69.25$ per cent.

No. 16, following table.

$a = 63.80$.
$g = 53 - (63.80 - 53)\ 1.25 = 39.50$ per cent.

In seven of the seventeen cases given the percentage of reducing matter calculated from the polariscope exceeds that given by the copper solution and by a mean amount of .539 per cent. In ten of them it falls short, and by an average of .938.

In many examinations made subsequent to the above the mean deviation has been even less.

Hence I can say that the method indicated will give results which in the mean differ by less than the half of one per cent. from the reduction tests. I regard my calculations from the polariscope equally as reliable as those made with the copper solution.

* Read before the A. A. A. S., Boston, 1880.

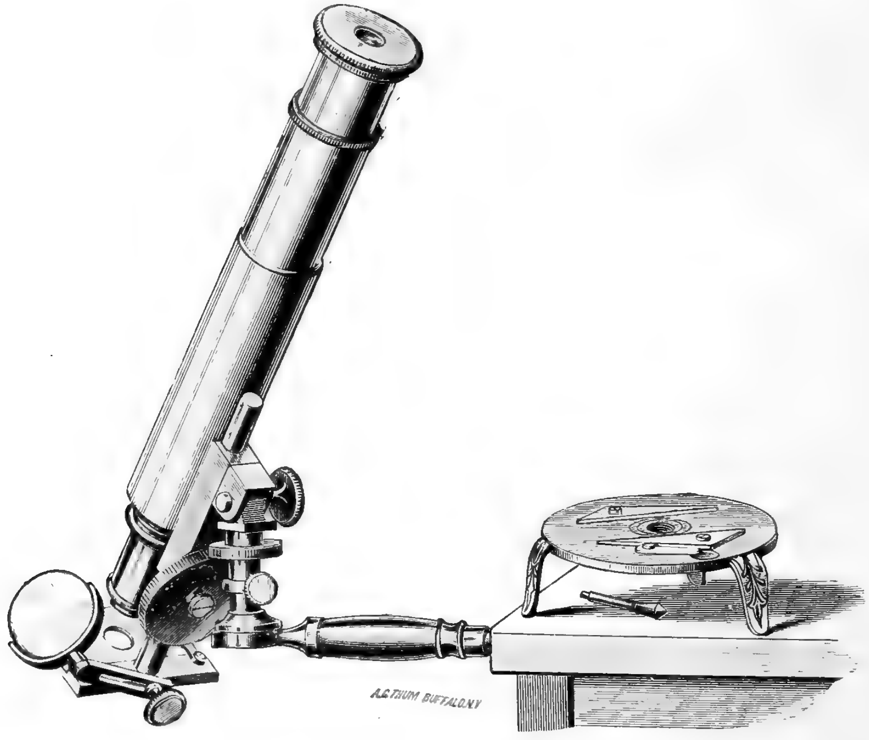
NEW PORTABLE MICROSCOPE.

We present with this number two illustrations showing a new form of portable microscope stand, designed by Mr. E. H. Griffith, and called by him the "*Griffith Club Microscope*," the chief merit of which appears to be its portability, and adaptability to certain positions, which are impossible with the ordinary instruments.

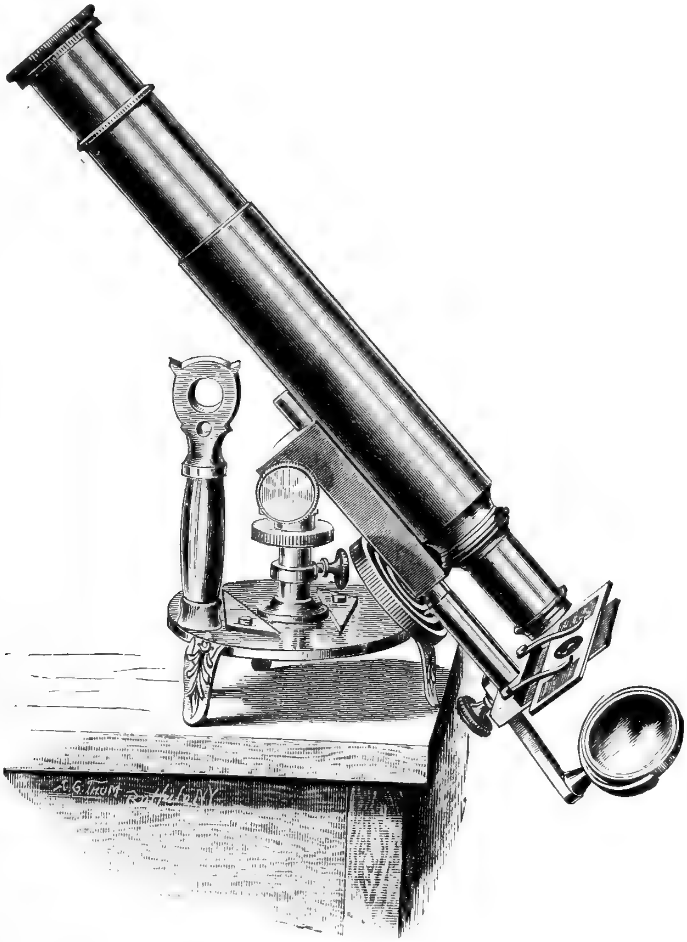
To those familiar with the use of the microscope an examination of the illustrations will suffice to arrive at a clear understanding of what Mr. Griffith has produced. It will be seen that much originality has been displayed, and that novelty of construction is a leading feature. The greatest innovation is the use of an ordinary self-centering turn-table for mounting, as a stand for the instrument; if, however, the turn-table is required for use, the microscope can be closed and used as a stand for the turn-table. The fine adjustment is also an original device of Mr. Griffith, and will be noticed as a large milled-edged screw in the cut. On the inner surface of this cir-



GRIFFITH'S PORTABLE MICROSCOPE. (Fig. 1.)

cular plate is a spiral groove into which works a pin controlling the stage. Mr. Griffith states that with this appliance, a very perfect focal adjustment can be obtained.

Illustration No. 1 shows the instrument attached to a table by a screw support, the mirror placed in position above the stage. As an adjunct to a dissecting table the Griffith microscope, thus used, would be found most useful, occupying no surface space. In excursions it could by the same means be attached to the side of a tree or to a fence. No arrangements have been as yet completed for the manufacture of this instrument, but it is believed they will shortly be made by a firm who will undertake to produce them at a reasonable cost, as Mr. Griffith has aimed to construct a serviceable portable instrument at a moderate price.



GRIFFITH'S PORTABLE MICROSCOPE. (Fig. 2.)

ON CHICKEN CHOLERA: STUDY OF THE CONDITIONS OF NON-RECIDIVATION AND OF SOME OTHER CHARACTERISTICS OF THIS DISEASE.*

BY M. L. PASTEUR.

I.

In the communication which I had the honor of presenting to the Academy in the month of February last, I announced, among other results, that chicken cholera originates in a microscopical parasite; that there is an attenuated virus of this disease, and that one or more inoculations of this attenuated virus may preserve chickens from death when inoculated with the virus of maximum virulence. On account of the striking similarity that these two forms of virus present with the effects of variola and vaccine in man, it becomes interesting to ascertain not only if the immunity from the more aggravated form of virus is absolute, for the regions of the body which have undergone the preventative inoculation, but also if this immunity exists in the system, no matter what portion of the animal may have been inoculated, and what may have been the manner of introducing the virus.†

To explain with brevity the results which I have to communicate, I may be allowed to use the word *vaccinate*, to express the act of inoculating a chicken with the attenuated virus. This being admitted, I may state, as the result of many experiments, that the effects of vaccination are very variable. Some chickens are little affected by the most virulent virus after one inoculation of the attenuated virus; others require two such inoculations, and even three. In every case, the preventive inoculation does some good, be-

* Translated from the *Comptes Rendus de l'Academie de Sciences*, of April 26th, 1880, page 952, by P. Casamajor. The translation of the first paper of this series appeared in the *Chemical News*, vol. xli., page 4 (July 2nd, 1880).

† From all I have seen and read of vaccine in man, and from my experiments on chicken cholera, I infer that *vaccine* rarely acts as a complete preventative. There are cases cited of vaccinated persons who have had the variola, and there are even cases of persons who have had it, afterwards, as much as three times.

cause it acts in a certain measure. Vaccination, then, may be of several degrees; but we may always succeed in completely vaccinating a chicken, which means that we can bring it to such a condition that it becomes incapable of being affected by the most virulent virus.

To make this matter clear, I will now give the results of experiments:—I take eighty new chickens (I call *new* those which never suffered before with chicken cholera). Twenty of these I inoculate with the most virulent virus, and they all die. Of the sixty that remain, I take another lot of twenty, and I inoculate them with that quantity of the most attenuated virus which the point of the needle will take up*—and not one dies. Are they then vaccinated for the aggravated form of virus? Some are and some are not, for if I afterwards inoculate these twenty chickens with the most virulent virus, six or eight of them will not die, although they may be ill, while in the first case every inoculated chicken died. I take again from the remaining chickens another lot of twenty, and these are vaccinated with the attenuated virus exactly as the preceding lot, and, a week afterwards, they are again vaccinated in the same manner. Are they now safe from the virulent virus? We now inoculate these twenty chickens with this virulent virus, and, instead of there being six or eight which do not die, there are twelve or fifteen. Finally, I take the twenty remaining chickens, and vaccinate them successively three or four times. If now I come to inoculate them with the most virulent virus, not one will die. In this case, chickens are brought to the condition of animals which are incapable of suffering from chicken cholera.

As to the cause of non-recidivation, I find it impossible to resist the idea that the microscopic germ, which causes the disease, finds in the body of the animal conditions suitable to its development, and that to satisfy the necessities of its life, the germ alters certain substances, or destroys them, which comes to the same thing, whether it assimilates them, or whether it consumes them with oxygen borrowed from the blood.

When complete immunity has been reached, the most virulent germ may be inoculated into any of the muscles without producing any effect. This means that the cultivation of the germ has become impossible in these muscles. They no longer contain food for the germ.

It is impossible to convey the impression that one receives from observing such phenomena. Here are twenty chickens which never had this disease. I inoculate them in their pectoral muscles or, still better, in the muscle of the thigh, so as to observe with greater ease the effect of the innoculation. The next day all the chickens are lying down; they are very lame and seem overcome by sleep. The inoculated muscle becomes of enormous size, and is profusely filled with the parasites. From time to time, a chicken dies, and, at the end of forty-eight hours they are all dead. We may take also twenty chickens, previously vaccinated several times, and inoculate them at the same time as the others, with the same virus, in equal quantities. The next day and the next, they are all alive and in good health; they eat and cackle as usual; the cocks crow; the inoculated muscles present nothing abnormal. There is not even a sign to show where the skin was punctured. This healthy condition remains permanent.

We may now inquire whether the impossibility of cultivating the parasite is not limited to the muscles which have been inoculated. This may be answered by introducing the deadly virus in the blood vessels and in the digestive organs. I have taken ten chickens, never before inoculated, and ten others inoculated several times with the mild virus. I have then injected the worst form of virus in the jugular vein of all these chickens. The first ten have died rapidly; many of them within twenty-four hours. The ten vaccinated chickens, on the contrary, have only been slightly ill from the incision of the skin and of the jugular vein, and were soon in good health. This shows that the blood of these ten chickens was itself *vaccinated*, which means that previous cultivation had deprived it of the materials fit for further developments of the germ.

As to the introduction of the parasite in the digestive organs, I have imitated the epidemics which depopulate poultry yards, by introducing the parasite in the food of the chickens. On the 11th of March I brought together twelve chickens, bought at the market that very morning, and twelve others, previously vaccinated several times. Every day I gave to these twenty-four chickens a meal of the diseased muscles of chickens, who had died from chicken cholera. Through the combs of the twelve chickens which had not been vaccinated I passed a platinum wire, so as to distinguish them from the other twelve. On the next day the unvaccinated chickens began to sicken and die. On the 26th of march the experiment terminated. Seven of the chickens that had not been vaccinated have died, and a *post mortem* examination reveals the fact that the disease was introduced in the system, either through the first portion of the alimentary canal, or, more frequently, through the bowels, which were highly inflamed, and sometimes ulcerated, in a manner which recalls the lesions of typhoid fever.* The five other unvaccinated chickens are more or less ill, one seriously so. As to the twelve vaccinated chickens, not one has died, and to-day † they are all alive, and in good health. We may now sum up the results as follows:

It is the life of a parasite, in the interior of the body, which causes the disease known as chicken cholera and which causes death by this disease. When the cultivation of this parasite cannot take place in the body of a chicken, the disease does not show itself. The chicken is then in the constitutional condition of animals which chicken cholera cannot attack. Animals in this condition may be said to be born vaccinnated for this disease, because the fœtal evolution has not placed in their bodies the proper food of the parasite, or because substances, which could serve as such food, have disappeared while they were yet young. We must not wonder that there are constitutions more or less apt to receive inoculations of certain kinds of virus, for, as was announced in my first note, the broth of beer-yeast is entirely incapable of supporting the life of the parasite of chicken cholera, while it is well adapted to the cultivation of a multitude of microscopical germs, notably of the bacteridia of carbuncular disease.

The explanation to which we are led by the facts already mentioned, of the different degrees of constitutional resistance of some animals, as well as of the immunity which chickens acquire by preventive inoculations, must seem a natural one, if we take into consideration that every cultivation modifies the medium in which it takes place. In the case of ordinary plants, the soil is modified, in the case of parasites, the animals and plants on which they live are also modified. The same thing happens with the liquids in which they live, in the case of ferments and other microscopical germs. The modifications which take place have this character in common, that new cultivations of the same species in these media soon became difficult or impossible. If chicken-broth is used for cultivating the germ of *chicken cholera*, and if, after three or four days, the liquid is filtered, to separate all the germs, and furthermore, if after this fresh quantities of the germs are placed in the filtered liquid, it will

* There are degrees of attenuation as well as of virulence. I will give explanations in a future communication.

* The blood is full of parasites, and the interior organs are frequently covered with pus and false membranes, particularly next to the intestinal pockets, through which the germ seems to have penetrated.

† April 26th.

be found incapable of producing the feeblest development. Perfectly limpid at first, the liquid remains indefinitely limpid.

We are led to believe that the cultivation of the attenuated virus in a chicken places its body in the same state as that of the liquid which can no longer sustain the life of the germ of disease. We may extend the comparison still further, for, if we filter the broth on the second day of the cultivation, instead of on the fourth, the filtered liquid will still permit the cultivation of the germ, but less readily than at first. This may enable us to understand that the cultivation of the attenuated germ in the body of a chicken may not have removed all the food for the germ. The remainder may allow a fresh cultivation of a feebler kind. This is the same as a first *vaccination*. Subsequent inoculations will remove progressively all the materials for the cultivation of the parasite. Through the action of the circulation, a time will come when any new cultivation on the animal will remain unproductive. Then the disease cannot recidivate, and the subject becomes perfectly vaccinated.

It may seem astonishing that the first cultivation could have stopped before all the food of the germ has been destroyed; but we must not forget that the germ is aerobian,† and that, in the body of an animal, it does not find the same conditions as in an artificial medium of cultivation, in which there are no obstacles to its propagation. In the body, on the contrary, it finds opposition from the cells of the organs, which are also aerobian, and are continually absorbing oxygen.

We might also account for the fact of non-recidivation by admitting that the life of the germ, instead of destroying certain substances in the body of an animal, on the contrary, adds other substances which act as an obstacle to its further development. The history of the life of these inferior beings, of all beings in fact, authorizes this supposition. The excretions due to vital functions often prevent vital functions of the same nature. In some fermentations, antiseptic products are formed while fermentation is going on, and even by the action of ferments, and these products put an end to further action, even if there are still substances left capable of undergoing fermentation. In the cultivation of our germ, there might, in the same way, be substances formed whose presence might explain non-recidivation and vaccination.

Our artificial cultivation of the parasite will enable us to examine this hypothesis. If we prepare an artificial cultivation of the germ of chicken cholera, we may evaporate the liquid *in vacuo* while cold, then bring it back to its original volume by the addition of chicken broth. If the extract contains a poison which destroys the germ, and if the presence of this poison is the cause of its non-development, the cultivation of the germ cannot take place in this liquid. On the contrary, the development does take place without difficulty. We cannot then believe that, during the life of the parasite, there are substances produced which prevent its further development. This is a corroboration of the opinion which we have expressed on the cause of non-recidivation in certain virulent diseases.

DENSITY OF LIQUID OXYGEN.—J. Offret has revised Pictet's calculation of the density of liquified oxygen and considers the method inadmissable. His own calculation gives 0.840.

EXPLOSIVE ANTIMONY.—A solution of crystalline antimony chloride and hydrochloric acid at 1.12 sp. gr. was prepared so as to stand at 38° B. On electrolysis with the Lechlanché element there was obtained in twenty to twenty-four hours a most explosive deposit.—E. MASCARENAS Y HERNANDEZ.

† Pasteur divides germs and other microscopic organisms into *aerobians* (requiring air to live) and *anaerobiæ* (which do not require air).—*Translator.*

ASTRONOMY.

THE Roman Academy of Sciences has awarded half of the King Hubert Prize to Dr. Wilhelm Temple, Director of the Acetri Observatory at Florence, for his observations on Nebulæ.

THE second Part of Vol. II. of papers relating to the Transit of Venus has recently been published by the Paris Academy of Sciences. It contains, among other things, the last of the Memoirs relating to the expedition to the island of St. Paul, the Meteorology by Dr. Rochefort, and the Geological Researches made at Aden, Reunion, St. Paul, Amsterdam and Seychelles, by M. Vélain. The first Part of Vol. III., which is to contain a report of the work done at Campbell Island, is in preparation.

THE "Reports of the Total Solar Eclipses of July 29, 1878, and January 11, 1880," forming Appendix III, to the "Washington Observations for 1876," has just been distributed from the Naval Observatory.

OWING to an error in the telegraphic dispatch, the discoverer of Comet *f*, 1880, was called *Pennule*. It should have been *Dr. C. F. Pechüle*, of Copenhagen. The comet seems to have two tails, one pointed towards the sun, and the other pointed about N. 15° *f*.

ASTRONOMICAL MEMORANDA: — (Approximately computed for Washington, D. C., Monday, February 7, 1881.)

Sidereal time of Mean Noon, $21^h\ 11^m\ 49^s$.

Equation of time, $14^m\ 25^s$.

Mean noon *preceding* apparent noon.

The *Moon* crosses the meridian at about 8.30 P. M. Full moon occurs on the 13th, and the last quarter on the 21st of the month:—New moon on the 29th.

Mercury is still evening star, following the sun by nearly an hour. He reaches his closest position to the sun on the 21st, and "greatest elongation" on the 22nd.

Venus is still the most conspicuous object in the evening sky. She increases her apparent distance from the sun until Feb. $20^d\ 7^h$, when she reaches "greatest elongation" East, an angular distance of 46° 34′.

Mars crosses the meridian at about 10 o'clock in the morning. He is nearly 23° south of the equator.

Jupiter and Saturn form with Venus an unusually good opportunity for the amateur astronomer to make use of his telescope in the early part of the evening. Jupiter and Venus will be in conjunction on the 21st.

Uranus is on the meridian about two hours after mid-night, and *Neptune* about half-past five in the afternoon. Uranus is in conjunction with the moon on Feb. 15th.

The *Comptes Rendus* for Jan. 3, 1881, contains a paper by M. Rouget upon a method for use at sea, and for travelers, explorers and others, for determining latitude and sidereal time, dispensing with the measurement of angles.

Two stars are observed having at a given moment, the same altitude: such observations are combined in pairs, and by merely noting the time which has elapsed between the two observations, a simple interpolation in tables prepared for the purpose will give the sidereal time and the latitude of the place of observation. Formulæ are given for the case mentioned above, and also for deducing the latitude and sidereal time from stars having the same azimuths, or azimuths differing by 180°. A succeeding paper by the same author extends the formulæ to the determination of longitudes, by employing observations of the moon.

W. C. W.

ON THE FIRST COMET OF 1861 AND THE METEORS OF APRIL 20.

By Professor Daniel Kirkwood.

M. Arago was the first to call attention to the frequent appearance of shooting stars in unusual numbers about the 20th of April, and to suggest the theory[1] that they are derived from a ring which intersects the earth's orbit. We are indebted, however, to the late Edward C. Herrick, of New Haven, for the collection of the principal facts by which the suggestion of Arago was fully sustained.

I.

THE GREAT METEORIC SHOWER OF APRIL 20, 1803.

More than thirty-six years after the event the old newspaper accounts of this wonderful display were sought out by Mr. Herrick and rescued from oblivion.[2] The following description of the phenomena as seen at Richmond, Va., is taken from the Virginia *Gazette*, of April 23, 1803.

"*Shooting Stars.*—This electrical phenomenon was observed on Wednesday morning last, at Richmond and its vicinity, in a manner that alarmed many, and astonished every person that beheld it. From one until three in the morning, those starry meteors seemed to fall from every point in the heavens, in such numbers as to resemble a shower of sky rockets. The inhabitants happened at the same hour to be called from their houses by the fire-bell, which was rung on account of a fire that broke out in one of the rooms of the Armory, but which was speedily extinguished. Every one, therefore, had an opportunity of witnessing a scene of nature, which never before was displayed in this part of the globe, and which probably will never appear again. Several of these shooting meteors were accompanied with a train of fire, that illuminated the sky for a considerable distance. One, in particular, appeared to fall from the zenith, of the apparent size of a ball of eighteen inches diameter, that lighted for several seconds the whole hemisphere. During the continuance of this remarkable phenomenon, a hissing noise in the air was plainly heard, and several reports, resembling the discharge of a pistol. Had not the city bell been ringing, these reports would probably have seemed louder. The sky was remarkably clear and serene, and the visible fixed stars numerous the whole night. We are anxious to know at what distance from Richmond this phenomenon has extended. It is hoped that persons who have remarked it in other places will not neglect to inform the public of the particulars; as such information may add in a great degree to the knowledge of meteorology.

Since writing the above, we have been informed that several of the largest of these shooting meteors were observed to descend almost to the ground before they exploded. Indeed, many of those which we saw, appeared to approach within a few yards of the house tops, and then suddenly to vanish. Some persons, we are told, were so alarmed that they imagined the fire in the Armory was occasioned by one of these meteors, and in place of repairing to extinguish the earthly flames, they busied themselves in contriving to protect the roofs of their houses from the fire of heaven."

The display was also witnessed at Raleigh, N. C.; Wilmington, Del.; Schoharie County, N. Y.; Portsmouth, N. H.; and at several points in Massachusetts. The descriptions of the shower as seen at these respective localities declare that, "the heavens seemed to be all on fire from the abundance of lucid meteors;" that they were "too numerous to be counted;" and that "part of the time the light was so great that a pin might be picked up on the ground." The shower, in short, would seem to have been one of the most extensive and brilliant on record, and hence to have been derived from a meteoric cluster of extraordinary density.

According to the catalogues of Biot and Quetelet[3] a great meteoric shower was seen in China on the 16th of March, B. C. 687. This date corresponds with the 20th of April in the nineteenth century. The display was therefore a shower of Lyraids. The interval between this extraordinary apparition and that of 1803 was 2490 years which may be regarded as a multiple of the true period.

The year 558 of our era,[4] midway between those brilliant displays, was the date of another great meteoric shower. The month and day are not given, but we may assume with reasonable probability that it was the great April display. Mr. Herrick found several other showers derived from the same stream. They seem, however, to have been of inferior brilliancy. They will be considered hereafter.

II.

THE FIRST COMET OF 1861.

The first comet of 1861 was discovered by Mr. Thatcher on the 4th of April. It was visible to the naked eye, and had a tail three degrees long. Its elements, calculated by Dr. Oppolzer, of Vienna, are as follows:

ELEMENTS OF THE FIRST COMET OF 1861.

Perihelion Passage	1861, June 3.
Longitude of Perihelion	243° 22′.
Longitude of Ascending Node	29° 55′.
Inclination	79° 45′.
Eccentricity	0.98345.
Semi-axis Major	55.67
Period	415.4 years.
Perihelion Distance	0.9207.
Aphelion Distance	110.425.
Motion	Direct.

Professor George Forbes has shown[5] that the comets of 1444, 1032 and 616 were former apparitions of this comet; the mean of the three periods being 415 years. The dates of ancient perihelion passages would therefore have been about A. D. 201, B. C. 214, and B. C. 629. In 1867, soon after the discovery, by Schiaparelli and others, of the connection between the comets of 1862 and 1866 with the August and November meteors, the probability of a similar relation between the first comet of 1861 and the meteors of April 20th was pointed out by Drs. Weiss and Galle.[6] The orbit of the comet nearly intersects that of the earth in longitude 210°, the point passed by the earth at the epoch of the April meteoric shower. An approximate equality of the periods of the comet and the meteoric stream was thus rendered highly probable.

The facts here collated constitute several very striking coincidences.

1. Dr. Oppolzer's period of the comet, derived solely from observations, is 415 years.
2. The mean period from 616 to 1861 was 415 years.
3. The interval between the great meteoric showers of B. C. 687 and A. D. 1803 is equal to 6 periods of 415 years.
4. The shower of A. D. 558 was midway between B. C. 687 and A. D. 1803.
5. The comet and the meteoric swarm seem to have equal periods.

It is by no means surprising that all returns of the meteoric group have not been recorded. The observations were restricted to the eastern continent; or, as

[1] In 1836.

[2] See Herrick's article in the Am. Journ. of Sci. for July, 1839, p. 358.

[3] Quetelet's Physique du Globe, p. 290.

[4] Quetelet's Catalogue.

[5] In a paper read before the Royal Society of Edinburgh, Feb. 16, 1880.

[6] Astr. Nach., Nos. 1632, 1635, and 1710.

Herrick has remarked, "some of them have doubtless been concealed by clouds, and others witnessed only by barbarians."

But between the great display of B. C. 687 and A. D. 1803, Professor Newton gives the following list of showers at or near the epoch of April 20,[7] viz.: B. C, 15, A. D. 582, 1093, 1094,[8] 1095, 1096, 1122 and 1123. The appearance of 582 ought probably to be rejected. It was two days from the epoch, and the record as quoted by Quetelet may have no reference to shooting stars.[9] The three remaining returns, B. C. 15, A, D. 1093-1096, and 1122-3, indicate a period of about 27 years. Now it is obvious that, at every close approach of meteors to the earth, many must be thrown into new orbits, all of which will pass through the point at which the perturbation occurred. It seems probable, therefore, that at some remote epoch a considerable cluster of this meteoric stream was thrown by perturbation into a new orbit corresponding to a period of 27 years. The change may have been produced by the earth during the passage of the meteoric swarm.

The facts which we have considered apparently indicate that the first comet of 1861, and the April meteors, formed a system in space before entering the solar domain; the latter moving in advance of the former at a distance comparable to the diameter of Neptune's orbit. By planetary perturbation the orbits were transformed into ellipses. If, as supposed by Professor Forbes, the disturbing body was an ultra-Neptunian planet in the vicinity of the present aphelion of the comet's orbit, said planet would probably describe less than 20° of its circuit during the interval between the nearest approach of the two bodies. But in aphelion the comet 1861 I, is too remote from the plane of the ecliptic to be sensibly disturbed by a planet moving in that plane. It seems more probable that the comet, as well as the meteoric group, owes the transformation of its orbit to one of the known major planets. Its radius vector when at its ascending node is about 10. In other words, its orbit approaches very near that of Saturn in longitude 30°. Now, it is remarkable that the interval between the perihelion passages of the meteors and the comet is almost exactly equal to two periods of Saturn. The meteors and Saturn were in the same longitude and in close proximity about B. C. 683, and the comet approached very near the planet at the same point about B. C. 625. The orbits may have been transformed into ellipses by Saturn's influence at these respective epochs. It may be worthy of remark that 11 times the period of the comet are equal to 155 times that of Saturn.

CHEMICAL NOTES.

ON BALLO'S SUPPOSED ADIPIC ACID OBTAINED FROM CAMPHOR.—On oxidation with chromic acid camphor does not yield adipic acid, but the same oxidation-products as with nitric acid. Chromic acid, however, converts the camphoric acid first formed completely into members poorer in carbon.—J. KACHLER.

ON THE REMARKABLE REDUCING PROPERTIES OF POTASSIUM FERROUS OXALATE, AND ON SOME OF THE REACTIONS THUS PRODUCED.—Ferrous oxalate is very permanent on exposure to the air, both in a wet and a dry state, and possesses very feeble reducing properties. The solution of ferrous oxalate in potassium oxalate, as well as the solid double salt, takes up oxygen greedily, and passes into potassium ferric oxalate. Its affinity for oxygen is equal to that of an alkaline ferrous hydrate, or of ammoniacal cuprous chloride, or of pyrogallic acid in an alkaline solution. The double oxalate exerts its reducing powers, not merely in alkaline, but in neutral, and even acid solutions. The solution quickly reduces platinum chloride and silver nitrate to metal. Silver chloride, bromide, and iodide are reduced completely, but more slowly. Copper acetate is reduced very slowly to cuprous oxide, and even to metal With the aid of heat mercuric chloride is reduced to metal. Recently precipitated Prussian blue is reduced to white ferro-cyanide of potassium. Indigo blue is reduced to white indigo, and solutions of sulphindigotic acid are rapidly decolorised.—J. M. EDER.

ON THE ACIDS $C_8H_{14}O_4$ FORMED FROM BUTYRIC ACID. Besides a volatile oily acid, probably identical with isocrotonic acid, there are formed by the reaction of suberic and bromobutyric acid, two acids agreeing in composition with suberic acid, but distinctly different from each other, and from the two isomeric acids produced by a corresponding reaction with brom-isobutyric acid. There exist, therefore, five isomeric suberic acids.—CARL HELL AND O. MULHAUSER.

A NEW SYNTHESIS OF PHOSPHENYL SULPHO-CHLORIDE.—Twenty parts phosphenyl-chloride are placed in a small flask with a reflux condenser, and five parts sulphur-chloride are slowly added by means of a dropping-funnel. After the reaction is over, the flask is set in a freezing mixture of Glauber's salt and hydrochloric acid. Pale yellow crystals of phosphenyl-tetra-chloride are formed, from which the liquid is separated by decantation, then shaken with water, dried and rectified. The yield is almost quantitative.—H. KOEHLER.

MORE PARTICULAR OBSERVATIONS ON THE ACTION OF POTASSIUM CARBONATE UPON ISOBUTYL-ALDEHYDE.—F. Urech places about 3 grms. pure isobutyl-aldehyde in a narrow test tube graduated in half millimetres. With a lens it is possible to read accurately quarter millimetres. After 3 decigrms. of finely-powdered recently-ignited potassium carbonate have been added, the tube is closed, set in a horizontal position, and the level is read off every five minutes for forty-eight hours. The liquid will be found to have sunk from 21.50 to 14.50 degrees.

AT a meeting of the Société Industrielle of Mulhouse, it was stated that tin sulphocyanide, formed by the double decomposition of calcium sulphocyanide and tin oxalate, is found very useful in calico printing.

For printing cotton with the azo-colors, Dr. Allrich proposes to dissolve 100 grms. of the color in five times its weight of water; then to make up a solution of sodium stannate or aluminate at 15° B., to every litre of which are added 20 grms. alizarin oil. Of this mixture 150 grms. are incorporated with the color, which is then thickened with starch and printed. After printing the pieces are steeped for an hour in lead or barium acetate or barium chloride at 5° to 10° B., and washed in cold water.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE:"

In reference to the correction of one of my statements made in your issue of the 29th inst. by Dr. Burt G. Wilder, I would say that I accept the criticism in all its bearings. The view which Dr. Wilder expresses regarding the upper wall of the third ventricle being constituted by the *ependyma* stretched across between the *habenulæ* of the pineal gland, was once entertained by myself (in accordance with the orthodox view of embryologists since the time of Rathke), and was the one which Dr. Wilder may perhaps recollect I expressed to him in conversation last year. I return to that view again. My abandonment of it was due to the confounding of two distinct questions, *i. e.*, the question of the true inner boundary of the floor at the lateral ventricle and the true upper and outer boundary of the third. The view I should have credited to Wilder and Hadlich, is that the *lateral ventricle does not* extend over the thalamus. My misapprehension of Wilder's statement is based on the fact that it rested on a verbal communication. That I mentioned it at all was

[7] Am. Jour. of Science, July, 1863.

[8] "At this period, so many stars fell from heaven that they could not be counted. In France the inhabitants were amazed to see one o thenmsfi great size fall to the earth, and they poured water on the spot, we hish their exceeding astonishment smoke issued from the ground with aoot f--ing noise."—Herrick's Catalogue. This record is of great interest as indr cating the fall of an aerolite during the shower of meteors.

[9] "A Soissons, on voit le ciel en feu. Une pluie de sang tombe sur Paris."

due to my unwillingness to adopt even unpublished views of others without at least giving formal credit. If my good intentions have in this instance had rather the effect of doing an injustice, that was not a matter of intent, but of error, and one I may claim an excuse for under the circumstances above explained.

Dr. Wilder refers to the absence of literary references in my short paper. This is in accordance with the fact that the paper was a provisional communication of results purely my own, and that quotations of the views of others were limited to such relating to collateral details or of works like those of Luys and Meynert, which are so much household words among cerebral anatomists that I thought a mention of their exact titles a useless affectation.

On reviewing the matter, I find that the relations are in every respect as Dr. Wilder gives them, viz.: 1st. That the lateral and third ventricles only communicate through the Foramen of Monro. 2d. That the medial aspect of the Thalamus only is in the third ventricle. 3d. That no part of the Thalamusis in the lateral ventricles. 4th. That the dorsal aspect of the Thalamus is neither in the third nor in the lateral, nor in any other ventricle.

My description of the third ventricle as a T shaped slit, requires this modification, that the vertical branch alone is ventricular, the horizontal being neither a part of the lateral nor of the third ventricle, but a *fissure* extending between the thalamus and the cerebral hemispheres.

While thus embryologically and morphologically the thalamus must be looked on as a distinct cerebral segment, yet in the higher mammalia (as I claimed some years ago) it has become practically a subsidiary ganglionic depot of the cerebral hemispheres, and thus assumes a position not without its analogies to that of the *Corpus striatum;* a view in full accord with that of Meynert.

In conclusion I would offer a formal apology for the erroneous interpretation I made of Dr. Wilder's views, and state that the communication I made was merely provisional, and intended to be followed up by more full essays on the different subjects mentioned therein, in which the necessary literary references will not be wanting.

I also trust that Dr. Wilder will, in his publication, enlighten us on the anterior termination of the "extraventricular" slit which extends over the thalamus and under the Fornix. I am unable to determine this question from my sections, which are chiefly made in the transverse direction, and in which the ependymal roof of the third ventricle was either absent or removed by the knife. This feature was in part responsible for my misapprehension of the shape of the third ventricle. Respectfully,

NEW YORK, February 3d, 1881. E. C. SPITZKA.

RECURRING PERIODS IN THE WEATHER.

To the Editor of "SCIENCE:"

Last year I published in the New York *Tribune* a table for the month of February showing the dates of rain and snow in that month for twenty years. I also pointed out that there seemed to be two well marked storm periods, about the 3rd and 20th of that month, when a storm might be expected. Since then I have made some corrections in the dates as then published and have extended my investigation to all the rest of the months. The result will be found in the table below; the table gives the dates of rain or snow as observed at Newburgh, N. Y. In all cases the blanks indicate that I had no observations for those dates. I would be very much obliged to any of the readers of "SCIENCE" who may have observations for these missing dates if they would publish them in "SCIENCE." For example, did it rain about 3rd of August 1862, May 1877, August 1873, August 1874, August 1876 and 1877, or about September 3, 1869? The missing dates from the 20th I would also be very much pleased to have supplied. An examination of the table will show that there seems to be two well marked storm periods in each month, and that a storm may be expected about the 3rd and 20th of every month. The crucial test for any theory concerning the weather is to see how accurately it predicts for any one place. It will readily be comprehended that the larger the area we predict for, greater is the probability of our predictions coming true, for if it does not storm at one place it may at another. Had I felt justified in using observations made in the vicinity of Newburgh, the table would have agreed much closer with theory, but I have only used the dates on which storms occurred at Newburgh. Besides, when the storm was very light near the 3rd or 20th, I have in some cases omitted it and recorded the date of the next storm. Thus, for example, it snowed at Newburgh December 21, 1880, but it did not last long, and I have recorded the heavier storm of December 25th; and in September, 1864, it rained before the 30th, but as it was very light, I omitted it and recorded the first rain of any amount after the 20th. However, my object will be accomplished if this article should direct the attention of observers to the importance of paying more attention to the recurring periods in the weather, on which Vennor has founded his predictions which have proved so true in many instances.

JAMES H. GARDINER.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, FEBRUARY 12, 1881.

It appears to be a fact not generally known in the United States that a prize is annually offered by His Majesty, the King of the Belgians, amounting to the sum of twenty-five thousand francs, for the encouragement of intellectual effort.

The intentions of the King were made known by a decree dated the 14th of December, 1874, inviting the authors of all nations to compete, and placing the settlement of the award in the hands of a jury appointed by His Majesty, composed of seven members, three of whom must be Belgians, and four foreigners of different nationalities.

The prize for the year 1881 will be awarded "to the best work on the means of improving ports established on low and sandy coasts like those of Belgium."

The original time for sending in these essays, which may be either printed or in manuscript, was the 1st of January, now last past, but we are authorized in stating that the time has been extended to the 31st day of March, 1881.

Foreigners desiring to compete for this prize are required to send their works to the Minister of the Interior at Brussels; but Mr. John Eaton, U. S. Commissioner of Education, advises competitors in the United States to forward their articles through the Department of State at Washington.

We are informed that the manuscript work obtaining the prize must be published in the course of the year following that in which the prize shall have been awarded, but in what manner the publication shall be made is not stated in the document placed in our hands.

Engineers and scientific men who would avail themselves of this opportunity must act promptly, and we would advise such to apply directly to Mr. John Eaton, of the Bureau of Education, in regard to any further information required for facilitating their work.

CHIMPANZEES IN NEW YORK.

THE last of the Chimpanzees at the New York Aquarium died on the 2d of February, of a throat affection. It was a remarkably well developed specimen. Its principle dimensions were, height (when standing) from heel to vertex 33 inches, distance from coccyx to vertex 20½ inches. Length of foot 6½ inches. Length of hand exactly the same. Its weight was twenty-four pounds. The brain was obtained by Dr. Edward C. Spitzka, making the third brain of this species in his possession. New York has been comparatively rich in anthropoids during the past three years. At one time there were five Chimpanzees and one Orang-Outang on exhibition together. The former lived about nine months. Altogether there have been at different times nine Chimpanzees at the Aquarium. Of the first pair, "Nip" and "Tuck," the former died of a tubercular meningitis, the latter passed successfully through an attack of Enteritis and later of Diphtheria, to die at Coney Island. A comparatively large animal standing over 3½ feet high, died of neoplasm in the lung. A female of depraved propensities such as have not yet been noted in anthropoids (devouring her own excrement), and a little two year old, one of the finest and most active anthropoids yet kept in captivity, died of catarrhal affections contracted at the seaside Aquarium, whither supposed business interest had directed they should go. Two well-developed animals, aged over two years, were sold to the Philadelphia Zoological Gardens.

A single survivor remained at the Aquarium. This animal had been in excellent health for a year and grown considerably during that period. About two years ago a new specimen arrived which had been brought from Africa, after a very stormy voyage, in a sailing vessel; it looked shrivelled and shrunken, weighed nine pounds, and was not expected to live. Those who saw it remarked that it bore the same relation to the other that a starved inmate of a baby farm does to a healthy, well-nourished child. But after a year it had outstripped its comrade in growth, and altogether gained fifteen pounds weight in the two years of its life of captivity. There must be considerable disparity between individual anthropoid apes in a state of nature, and this observation seems to confirm it,

TRICHINÆ IN PORK.

Dr. Ed. W. Germer, Health officer, of Erie, Pa., sends to us a portion of trichinous pork, as a sample of meat which infected a family of seven persons with trichinosis. The pig in question was raised with another, both being fed with the same food and reared under the same conditions. The pigs were killed at the same time, and an examination by Dr. Germer showed that one of these pigs was infected with trichinæ while the other was free from the parasite.

The owner of the diseased pig, his wife and two children were all taken sick simultaneously, and were treated for typhoid fever. Later three persons visited the house and were all seized with the same symptoms. The attending physician attributed the trouble to a well which supplied the family water. The mystery was solved by Dr. Germer who made the discovery of trichinous pork, and under his treatment the patients recovered. Dr. Germer suggests the possibility that many cases of trichinosis occur which are treated for other diseases, and trusts the time is not distant when young physicians will purchase a microscope before buying a gold watch or a gold-headed cane. We have examined the sample of trichinous pork, and confirm Dr. Germer's report; stripping a portion of the sarcolemma from the muscle we found seven trichinæ in the field of the microscope, using a ¼th objective. The trichinæ were in a free condition without cysts, and very transparent; for this reason they could be seen only by making very thin sections,

and would probably have been passed over by one making a careless examination. The Medical *Presse* of Vienna reports 80 cases at one town and 40 at another city, and the more recent fatal cases on board the British School ship *Cornwallis* would appear to suggest the importance of an official examination of all pork to be used for food.

PHILOSOPHICAL SOCIETY OF WASHINGTON.

At the one hundred and ninety-second meeting of the Philosophical Society, of Washington, a very interesting communication was read by Prof. J. W. Chickering, entitled, "Notes on Roan Mountain, North Carolina."

The Appalachian chain with its undulating line of 1300 miles from the promontory of Gaspé on the Gulf of St. Lawrence to Georgia and Alabama, beginning as a series of folds of moderate height, increases in complexity and altitude from north to south, attaining its greatest elevation in the Black Range of North Carolina. Following it from Gaspé to the Hudson we find the single chain of the Green Mountains reaching its extreme height in Mt. Mansfield, 4430 feet; the outlying cluster of the White Mountains with Mt. Washington, 6288 feet, and others exceeding 5000 feet; Mt. Katahdin, in Maine, about 5200 feet; the Adirondacks, with Mt. Marcy, 5379 and the Catskills considerably lower. From the Hudson to New River, Va., a distance of 450 miles, it gradually gains both in width and altitude. It consists of many parallel ranges with fertile valleys between, of which the great Valley of Virginia is the largest and best known, and all in reality a part of that Piedmont region. In Pennsylvania the summits vary from 800 to 2500 feet. Towards the south the chains become more numerous and indented, and in Virginia the Peaks of Otter reach 4000 feet. The extreme eastern range is called the Blue Ridge, the extreme western the Cumberland Mountains, or more properly *plateaus*, while the high range or ranges between is in general called the Alleghenies.

From the New River southward, the system becomes more complex. The main chain hitherto called the Blue Ridge is deflected to the west, and for 250-300 miles in a circuitous chain under the names of Iron, Stone, Bald, Great Smoky and Unaska Mountains joins the boundary between North Carolina and Tennessee, rising frequently to a height exceeding 6000 feet. The more easterly range retaining the name of Blue Ridge, having its southern terminus in Caesar's Head in South Carolina, turns abruptly to the northwest and reaches even loftier altitudes, Mitchells Peak being accredited with 6717 feet. In North Carolina these two ranges are more than 50 miles apart, are partially connected by transverse ranges, and for more than 100 miles constitute a great central plateau like that of Colorado on a small scale.

The eastern chain or Blue Ridge is still the watershed, and on the Atlantic slope gives rise to the Roanoke, Catawba, Broad, Saluda and Savannah rivers. On the other side, this area of mountains and plateaus is separated by transverse chains into many deep basins. At the bottom of each runs one of those mountain streams, the New Watanga, Nolechucky, French, Broad and others. These are compelled to cut their way to join the Tennessee through gaps, gorges and defiles in the heart of this great chain, giving us some of the most picturesque scenery to be found on the continent.

In the midst of this region with all three ranges in sight stands Roan Mountain (a Laurentian mass), the State line crossing it at an altitude of 6391 feet. I desire to call attention to some of the peculiarities of the region as contrasted with the northern Appalachians.

Standing upon the summit of Roan we look into seven different States, and command a horizon of 30 to 80 miles. On the north and west the eye catches the Cumberland Range on the horizon, and in the interval the great Cumberland plateau, and and many other ranges, but all as level as if designed for railroad embankments—sometimes not a peak to be seen in 40 miles of crest. On the south is a wilderness of mountains. Guyot gives fifty to sixty with altitudes exceeding 6000 feet, and yet the highest is only 6717, and perhaps forty of them between 6000 and 6500, and hundreds of others 5000 +. The valleys rarely go below 3000 feet. The railroad after leaving Lynchburgh in a few miles reaches 1000 feet, and from that point for nearly 300 miles rarely goes below 1500 feet, and at one point reaches 2550. The true Piedmont region, extending through to Virginia, North and South Carolina, Georgia, Alabama and Tennessee, at an elevation of 1500 to 2500 feet, offers as attractive a region for health and comfort as can be found on the globe.

Uniformity of temperature. During nine weeks the mercury indicated once 75°, seven times 70°+, once 45 , three times 50°—, the general daily variation being between 55° and 65°. The spring a few rods from the hotel, has a temperature of 45°. Equally remarkable was the uniformity of atmospheric pressure, the highest barometer being 24 19, and the lowest 23.87. No wind had a velocity greater than 20 miles an hour, and seldom reached ten miles. The last time I was at Mt. Washington, in August, the mercury was 36° and the wind 40 miles.

Fertility of summit. Instead of the upper 1000 feet being, as in most of the higher northern peaks, a pile of barren rocks with lichens their only vegetation, the summit of Roan and many other peaks is a smooth grassy slope of the most vivid green, dotted with clumps of *Alnus viridis, Rhododendron Catawbiense*, the soil one or two feet deep and black. How this amount of humus was accumulated, and what cause destroyed the forests which its existence seems to indicate as formerly existing are questions not easily answered. The valleys are very fertile and adapted to almost any crop.

At an elevation of 3000 to 4000 feet occurs a belt of the most magnificent forest trees I have ever seen. Hundreds of chestnuts, sugar maples, lindens, tulip trees, yellow beeches, and buck-eyes were seen from four to seven feet in diameter, and rising 70 to 80 feet without a limb. One chestnut measured 24 feet in circumference, and one black cherry 19 feet. Thorn bushes were as large as apple trees, and with dwarf buck-eyes and yellow beeches looked like old orchards of vast extent in the higher levels.

Flora. Ascending the mountain, the vegetation takes on a northern aspect. Hemlocks abound till near the summit, where they are replaced by Abies Fraseri, the characteristic spruce of these summits. Anemone nemorosa, Oxalis acetosella, Rubrus ordoratus, Aster acuminatus, Habenaria orbiculata, Ribes lacustris and prostratum, Veratrum viride, Lycopodium lucidulum and similar species, remind one of the woods of Maine and New Hampshire. The peculiar flora of the upper 1000 feet greatly resembles in habit those of the White Mountains, but very few are of the same species. Paronychia argyrocoma, Alnus viridis, and a species of Lycopodium are almost the only plants occurring to me as common to the two localities. Anemone Grœnlandensis is replaced by A. glabra; Solidago thyrsoidea by S. glomerata. The species peculiar to these mountains in general are hardly sub-alpine, and thus continuous with similar species further north but rather apparent instances of local variation, many species being confined to very narrow localities. The same is true of the molluscs. On Mt. Washington, a few rods will sometimes give the same plant in bud, flower and fruit, as a north or south exposure, a precipice, or a snowdrift, may retard or accelerate growth. But on these southern mountains no such difference obtains any more than in the valleys below.

On this communication Professor J. W. Powell remarked that the uniformity of altitude of the peaks is a a feature resulting from the fact that the mass out of which they have been carved by erosion possesses a plateau structure. The elevation of that region was dis-

tributed in its effects with an approach to uniformity over a wide extent of country, and was unaccompanied by those sharp flexings or the protrusions of abrupt granitic cores which are encountered in some portions of the Appalachians and other mountain regions. The individual masses and ranges in the Cumberland region are the work of erosion acting upon a broad platform, excavating wide valleys and narrow gorges, leaving the peaks and ridges as cameos and mere remnants of the general degradation of the entire region. Professor Powell exemplified the process by citing the Uinta Mountains as a broad platform similarly carved by an enormous erosion.

Mr. Lester F. Ward then read a communication entitled, "Field and Closet Notes on the Flora of the District of Columbia." Mr. Ward's paper was more comprehensive than its title indicated. He read extracts from a local monograph which he has been preparing on the Flora of the District of Columbia. The work has been done by Mr. Ward in his usual energetic, thorough, and philosophical manner, and presents many points of interest. It will be published in full by the Society.

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON.

The Society met in the lecture room of the National Medical College on Tuesday evening, February 1, Major J. W. Powell in the chair. By the provisions of the Constitution the retiring President is required to deliver his annual address at the meeting succeeding that held for the election of officers, and to review therein the work of the Society during the past year. As before mentioned, the reasons for the publication of elaborate proceedings, existing in the case of other societies, do not obtain here. The President, therefore, in connection with his address, had prepared a pamphlet of 100 pages, in which were embodied abstracts of every paper read during the two years of the Society's existence, together with a brief history of its formation, the two annual addresses, the constitution, and the list of officers and members. The whole constitutes a very important contribution to knowledge.

Major Powell thus presented a classification of the papers and discussed the several subjects treated in their order, namely: Archæology, ethnography, linguistics, biology, philosophy, technology, sociology, and mythology. As the address will appear in full as a part of the pamphlet, it is not necessary to present an abstract.

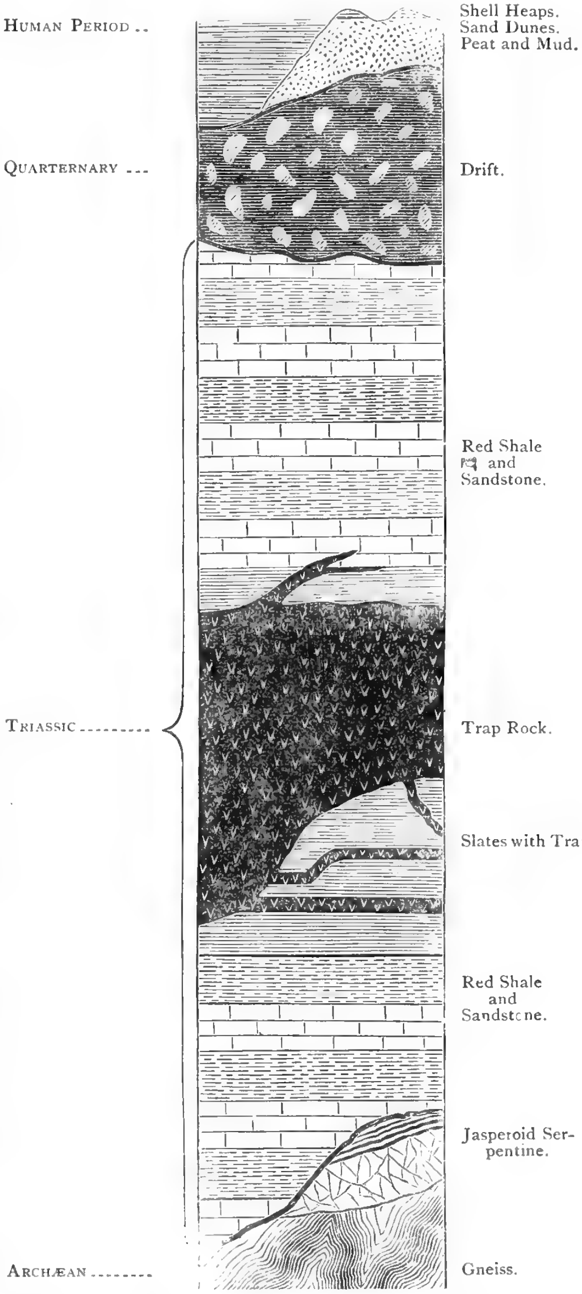
Determination of Gold and Silver in Alloys, after Quartation with Cadmium.—Two portions of the alloy, each of 0.25 grms., are weighed off and placed with the cadmium in small porcelain vessels. A piece of potassium cyanide is melted in a porcelain capsule over the flame, and the metal thrown in. The melting together takes place readily, and is complete in a few minutes. By changing with two or three porcelain capsules, and having a vessel with warm water at hand, in which the melted portion is dissolved when sufficiently cool, twenty to thirty meltings can be executed in an hour. The two metallic granules are now thrown together into a small long-necked flask, in which is nitric acid of sp. gr. 1.30; a piece of wood charcoal is introduced to prevent bumping—which would rupture the globules—and heat is gently applied. The first solution lasts rather long, according to the proportion of gold; *e.g.*, an hour in case of fine gold. The solution is poured off, the boiling repeated with nitric acid of sp. gr. 1.3 for ten minutes, the liquid again poured off, the globules rinsed with hot water, boiled for five minutes with water, which is poured off, and the flask filled with water is inverted into a porous earthern crucible, dried, ignited strongly, proceeding as in cupellation. In most cases the globules can be weighed separately. Silver is determined in the solution of titration with ammonium sulphocyanide according to Volhard's method.—Fr. Kraus.

A SKETCH OF THE GEOLOGY OF HUDSON COUNTY, N. J.*

By Israel C. Russell.

An outline of the geology of Hudson County, N. J., is delineated in the accompanying generalized section.

Fig. 1—Generalized Section of the Rocks of Hudson County, N. J.



At the base of the series is crystalline gneiss of Archæan age, which is exposed in a few reefs along the shore of the Hudson in Jersey City. These rocks are composed mainly of quartz, feldspar and mica, and form highly crystalline gneiss, mica schist, hornblende schist, etc., and are not to be distinguished from the rocks of

* Taken from a paper published in the Annals of the N. J. Academy of Sciences, Vol. II., No. 2, pp. 27-80.

the same formation exposed so abundantly on Manhattan Island.

Associated with the crystalline Archæan rocks that to a limited extent border Hudson County on the east, are beds of quartzite and serpentine, exposed in the bluff known as Castle Point at Hoboken. This premontory is about thirty acres in area, and is limited on the east by bold bluffs of serpentine. The rock here exhibits considerable variety, being sometimes yellowish and dull in appearance, and so earthy as to crumble between the fingers; again it is compact, dark green in color, and furnishes an ornamental, although inferior, building stone. This rock is a silicate of magnesia containing chrome-iron in scattered grains, and furnishes also the minerals *marmolite, brucite, nemalite* and *magnesite.*

The quartzite or jasperoid rock, occurring on the southern slope of the serpentine, in the neighborhood of the Stevens Institute, has, together with the serpentine, been referred to the Archæan series, but as the exposures are now obliterated little can be said concerning it.

TRIASSIC ROCKS.

In Hudson county we have a portion of the eastern border of the Triassic formation which forms a band thirty miles broad across the State. In general with the Triassic formation in New Jersey and the Connecticut Valley, the rocks are here felspathic sandstones, slates and shales traversed by sheets and dikes of trap. The sedimentary rocks occupy nearly the whole area of the county and dip uniformly to the northwest at an angle of about 15°. The sandstone is largely composed of granules or fragments of felspar, cemented by oxide of iron to which the reddish or brownish color of the rock is due; this is the stone so largely used for architectual purposes in New York and the neighboring cities. Traversing these inclined beds of sedimentary rocks, and in a general way conformable with them, are sheets of intrusive trap, which now owing to unequal erosion, form the most prominent features in the topography of the county. This statement holds good, also, for the entire Triassic area in New Jersey, and with more or less accuracy for this formation in general along the Atlantic slope. The main trap ridge in Hudson County, composing the highland known in different portions of its course as Bergen Hill, Jersey City Heights, and the Heights of Weehawken, is continued northward with increasing height, and forms the bold picturesque shore of the Hudson as far northward as Haverstraw. The outcropping edge of the trap, especially in Hudson County, has been abraded by glacial action so as to form an irregular, badly drained, plane surface. Although in a general way following the bedding of the associated slates and sandstone, the trap sheet is really unconformable to them and breaks across their bedding in various places. From both the upper and lower surfaces of the main trap sheet smaller sheets and dikes of molten rock have been intruded among the stratified beds. Examples of these branches from the principal mass may be seen at the base of the cliffs along the west bank of the Hudson, from Hoboken northward. Secondary sheets originating from the upper surface also appear on the western border of Bergen Hill, where they have been accented by erosion. The intrusive nature of the trap sheets and dikes is shown by their crystalline structure, their unconformity to the inclosing stratified beds, and by the metamorphism produced in the strata with which they have come in contact. A section exposed in the cliffs bordering the Hudson a few miles north of Hoboken, is given in the following figure, and illustrates especially the abrupt manner in which the New Jersey Triassic area is cut off along its eastern border.

In the diagram D represents the sheet of drift that covers the eroded surface of the hill, and S the slates that unconformably underlie the trap into which a small

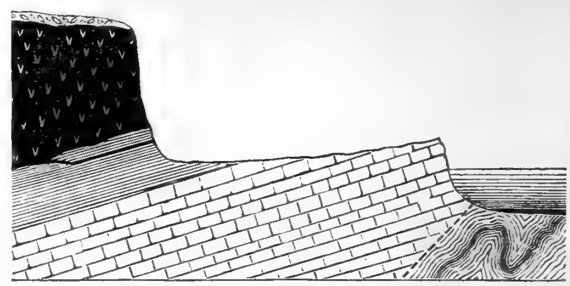


FIG. 2—SECTION AT DOG'S POINT, WEEHAWKEN.

secondary sheet of the crystalline rock has been intruded. Beneath the slates are beds of light colored felspathic sandstone ending in a cliff at the water's edge; the whole series has the usual dip of 15° N. W.

The irregular line formed by the eastern boundary of the trap is caused, at least in two instances, by sheets of trap that leave the main mass at an angle and stand out in ridges tangent to the principal line of cliffs; examples of this feature, which is difficult of description withou illustrations, may be seen at Kings Point, Wehawken and Fairmont Hill, Jersey City.

POST-TRIASSIC HISTORY.

No records are found in Hudson County, of the Jurassic cretaceous or Tertiary periods during all these geological ages; the area under discussion must have been a land surface exposed to subaerial denudation. The same destructive agencies were at work, too, with accelerated energy during the Quaternary period. The result is that we have but a decimal portion of the original Triassic formation remaining.

During the Quaternary, northern New Jersey, in common with a great area in the northeastern part of the continent, was buried beneath glaciers of great thickness. In Hudson County the ice-sheet moved from north-west to south-east, ploughing out in its journey the soft Triassic shales and sandstones, and grinding off the projecting ridges of trap with a force so irresistable that a mountain-ridge like the Palisade range could not deflect it from its course. When the climate ameliorated and the glaciers retreated northward, the hard crystalline trap was left with a polished surface that glitters in the sun light, and is crossed by deeply engraved lines that faithfully record the direction from which the glaciers came. In places the rock rises into smoothly rounded hillocks, forming typical *roches moutonnées.* The load that the glaciers carried was spread over valleys and uplands, forming a continuous sheet of glacial drift, which now composes the immediate surface of a large portion of the county. This glacial drift is generally a tenacious clayey deposit, at times fifteen or twenty feet thick, of a reddish color, derived from the debris of Triassic shalas and sandstones that enter largly into its composition. Scattered through it are boulders of trap, sandstone, slate, etc., that have been transported but a short distance, and others of gneiss and conglomerate, the parent ledges of which are thirty or forty miles to the northwestward. Hudson county also furnishes examples of modified drift, consisting of irregular layers of sand, gravel and small boulders, all well rounded and plainly assorted and deposited through the agency of running water.

More recent than the glacial deposits are the sand dunes that skirt the base of the upland on all sides. Again more recent than the hills of aeolian sand are the many deposits of peat and mud still in process of formation along nearly the whole water-front of the county.

The bed-rock in Hudson county is, in most places, excepting on the uplands, deeply covered by Quarternary and recent deposits. The topography of the rocky floor of the county and of the neighboring portions of New

York, would not only be of great interest to the geologist but of direct economic importance to all interested in shipping, harbor improvements, reclamation of land, etc. The records of deep wells and soundings in the salt marshes that have a bearing on this subject are tabulated in the paper published by the Academy. On the Newark Meadows and in Newark Bay the rock bottom is from two to three hundred feet below the present surface. East of Bergen Hill soundings show a depth to rock nearly as great. The following list taken from the tables mentioned above, give some of the soundings on the borders of the deeply eroded channels of the Hudson, East and Harlem rivers :

Hudson River, foot of 23d st., 250 feet from the east building line of the river street	175 ft. to rock.
Hudson River, foot of Bethune st., 20 ft. W. of bulkhead line	176 ft. rock not reached
Hudson River, pier 60 (old No.), 20 feet W. of bulkhead line	175 ft. to rock
East River, N. Y. Tower of Brooklyn Bridge	107.4 ft. to bed rock
East River, Brooklyn Tower of Brooklyn Bridge	88 " "
East River, pier 41, N. Y , 200 ft. from the building line of South st.	91 " "
East River, pier 18, 200 ft. from the building line of South st.	60 " "
Harlem River at High Bridge, centre of river	70 ft. rock not reached
Harlem River, Madison av. Bridge, centre of river	75 " " "
As shown on the Coast Survey Charts of New York harbor, the water in the Hudson off Castle Point is	50–65 ft. deep
In East River, W. of Blackwell's Island	107 " "
In East River, at Hell Gate	121 " "
" " near Ward's Island	170 " "
In New York Harbor	60–80 " "
In the Narrows	60–116 " "
In the Kill Von Kull	25–54 " "
In Arthur's Kill	20–35 " "

These measurements, none of which give the maximum depth of the old channels, clearly prove that the drainage system about New York was at no very distant time several hundred feet below the present water surface. It might be shown with equal certainty that we are living many thousands of feet below what would have been the surface of the county had there been no erosion.

THE SOULS OF PLANTS AND ANIMALS.

By the Rev. Dr. Thomas Hill.

The only things concerning which we can arrive at absolute certainty are space, time and spirit. Their existence and some of their attributes are announced in every act of self-consciousness. Their existence and attributes are not matters of inference, but of direct sight. Matter, on the other hand, can substantiate its existence only by inference from these primal truths of space, time and spirit. All natural sciences are matters of mere deduction from the data furnished by mathematics and mental philosophy. All the business of life, (our manufactures, commerce, history), relating primarily to material things, rests in the same way, ultimately on truths of space, time and spirit ; that is on mathematics and philosophy. The conclusions at which we arrive in the historical and natural sciences are therefore more or less probable ; and the probability may reach a degree that is practically indistinguishable from certainty. I am practically as sure that this sheet of paper would burn if I held it in the gas jet, as I am that two straight lines cannot enclose a space. Nevertheless the first truth is a matter of contingency and probability, the second of absolute knowledge. These truths of absolute certainty, of direct intuition, concerning space, time and self-conscious mind, are not contingent ; they remain true, though heaven and earth pass away, and the perception of them is that which puts the stamp of immortality on the human mind.

But in addition to these fields of direct sight, the three fields of truth outside the conscious mind, are of the highest value. In the first place the certainty of the existence of other minds, is as near absolute certainty as it is possible for a truth of inference to be. That there are other men about me, and there is an Infinite Mind above us all, are truths which are practically as certain as the axioms of geometry. In the second place my fellow men are acting and have been acting, thinking, writing, painting, composing, legislating, warring and making peace, manufacturing and inventing for thousand of years ; and the study of their history is the richest and most fruitful method of developing my own powers, and learning to know myself. In the third place the field of space and time in which their history is cast is full of this wondrous matter, which gives them their opportunities, their means, their tools ; without it mental or moral life is inconceivable ; consciousness itself is awakened to activity only through contact with matter ; space and time are visible only through motion as a phenomenon of matter.

Here then is a great object of study, worthy of man's thought. Socrates was fearful lest Plato should spend too much time on questions relating to the measurement of matter ; Dr. Johnson in the Rambler carried Socrates's implied censure much farther than the old philosopher himself would have done. Swift in his voyage to Laputa satirizes the students of physical science ; the newspapers of our own day indulge occasionally in laughing at the technicalities of the scientific man ; even men as wise as the Autocrat of the Breakfast Table utter occasional words of disparagement in speaking of scientific pursuits. But Plato's geometry has done as much for the intellectual and purely spiritual development of our race as Socrates's morality ; and the physical philosophers of Europe, during the past three centuries, have, despite their own frequent ignorance of spiritual things, been of immense advantage to spiritual philosophy.

The relations of space are the earliest object of our scientific research. The first really intellectual ideas in a child's mind are those of geometric form. Hence all sciences that flow directly from geometrical relations are likely to be earliest developed. Mechanics preceded chemistry, and the classification of plants and animals by their outward forms preceded the knowledge of physiology, animal or vegetable.

Let us look then a moment at the geometrical study of material things, and see what it involves. Material forms suggest to the child the consideration of shape. He early learns to abstract form from the outward things and compare likeness in form only. He is but a few months old when the smallest drawing of a man, a dog, or cat, is recognized at sight. In a few years he takes the further step of looking by reason beyond the picture of imagination, and seeing the unimaginable realities in space itself. He conceives, for example, a sphere. But that portion of space which lies in a given sphere, surrounding a given point, has no properties by which it is distinguished from other parts of space. This is the Leibnitzian argument by which some modern writers would disprove the existence of space ; that its parts are indistinguishable and therefore coincident. But the geometer answers : No ! by an act of mind I seize upon any point of space and hold it as the centre of any sphere I wish to consider. When he has thus seized upon and considered a portion of space, bounded and separated from the surrounding space, by an act of his pure intel-

lection, he can communicate his thoughts to his fellow-men in either of two ways; first, scientifically by the medium of conventional symbols or language; and second, artistically, by a model or a drawing. This second method reaches a larger audience. What I write concerning a sphere, for example, can be understood only by those who have learned the language in which I write. But if I illustrate my propositions by good drawings or good models, the thought will be grasped by persons unlearned in mathematics—and persons of all nations, whether they understand English or not.

A form or model is therefore the clearest and most complete statement of a mathematical truth. Nor can a person give a more convincing proof of his understanding a truth than his ready and accurate drawing of an original diagram illustrating it. When we see material particles, the fine particles of crayon, for example, on the blackboard, obeying geometrical law, we recognize at once the expression of geometric thought. Law is a mental reduction of particulars to mental order. A geometric locus is a space in which each point is mentally referable to a single proposition; that is, a space in which the position of every point can be mentally grasped and defined by giving properly the position of one of them. When therefore we see numerous particles of matter conforming to a geometric locus, we are forced to believe that that mass of matter was moulded, directly or indirectly, by a mind which comprehended the law of the locus; and in the moulding of it, enounced the condition which defines the position of its points. The enunciation of a thought can come only from a mind comprehending that thought; and the formation of a geometric figure is the clearest enunciation of a geometric thought.

In the physical forces, therefore, which govern inorganic matter, is revealed the existence of a guiding intellect, since the forces are constantly producing perfect geometrical forms or leading to harmonious arithmetical relations. If we are forced to believe that gravity and chemical differences and chemical affinities inhere in matter, we must still, from the geometrical and algebraical powers exhibited by these forces, believe that they were bestowed upon matter by an intelligent power, who foresaw and comprehended their effects. The study of the natural sciences might otherwise well be given over to the reproach of Dr. Johnson in the Rambler, and Swift in the voyage to Laputa. Without a faith that law lies hidden in the material world, all the efforts of scientific explorers would be paralyzed; and without faith that that law is the choice of infinite wisdom, and adapted perfectly to fulfil the purposes of infinite love, the success of the scientific explorer in discovering it would be robbed of its highest and peculiar value.

In fact, the physical forces governing inorganic matter, acting under definite laws, and tending towards a state of stable equilibrium, nevertheless show in the intellectual, the geometrical and algebraical nature of those laws, a spiritual origin; they show that, however independent of will we may now conceive them to be, they nevertheless are the embodiment of thought; and we know of no way of embodying thought without a volition.

But if the Creator has thus stored in crystallizable matter, in a manner transcending all our thoughts, forces which carry out His geometrical and algebraical conceptions, much more marvellous and beautiful are the modes in which he has imparted to the souls of plants and animals (if I may thus extend the use of the word soul) the power of carrying into execution more complicated geometrical and algebraic plans.

For in every organized being, plant or animal, there is a guiding principle which we may call, if we please, a soul, which causes the forces of matter no longer to act under laws tending towards stable equilibrium, but under a variety of laws, different in each species, tending not towards stable but towards unstable equilibrium. This guiding principle has in itself no forces. The most careful investigators of the phenomena of organic growth fail to find any evidence of vital *force*, although there is abundant evidence which must convince the most careless observer that there is in organized growth a vital *guidance* of force peculiar to each species of plant or animal, which I cannot conceive as inherent like the physical forces in matter and which I therefore, must attribute either directly to the Deity, or to an animal or vegetable psyche, empowered by him to carry out these higher geometric forms, just as in each species of matter he has implanted the ability to carry out the simpler geometrical forms of crystals.

There are those whose philosophy differs from mine, and who hold to the opinion that the vital guiding principle in organic growth, and even the rational soul of men and animals are inherent in matter, in the same manner as the forces which they guide are inherent in matter. According to this philosophy the vital principle and the rational principle, inherent in matter, are usually latent and are brought into operation only under peculiar combinations of circumstances.

Now even should we grant the soundness of this view, I should still find it necessary, for the explanation of the logical series of vegetable and animal forms, to suppose that this universally diffused vital principle originally sprang from an intelligent self-conscious being who comprehends the laws of geometry perfectly; and who has expressed certain of his geometric thoughts through the psyche or soul of plants and animals, whether we suppose that psyche diffused but latent through all matter, or confined to the organisms in which it is patent.

The nature of this psyche, of course, transcends our knowledge. We recognize it only through its operations; and consciousness aids us in our attempts to understand it only so far as to show that its effects are intellectually identical in geometric form with the product of our geometric imagination. But we cannot suppose the psyche of the plant or animal conscious of all the thoughts which it develops, since we, whose psychical development is evidently vastly higher than that of any other terrestrial beings, are not conscious of the geometric law of our own bodies, which our souls unconsciously fulfill; not only during the period of our growth, but daily as we supply by nutrition the daily waste of the frame.

The fact that the plant or animal may, without the exertion of any mechanical force, guide the forces of electricity, and light and heat and chemical affinity, to the building of peculiar forms imprinted on its own soul, may receive a coarse illustration from the operations of the steam-engine in which, by delicacy and accuracy of workmanship, the direction given to the power can be changed by a force infinitesimal in comparison to the force exerted by the engine. The chemical forces which govern the organogens in their compounds are always the same, but the results vary for each individual plant or animal, and the law which those results indicate is different for each species. The forces, building out of these few simple elements so great a variety of forms, are tremendous in their energies, and their existence is forced upon the attention of the naturalist; but the vital force, if such a thing exist, which guides these tremendous powers and determines what result they shall bring to pass, has eluded the sight of the most careful and accurate observers. The nicer the investigation into the phenomena of organic form, the more wonderful do the results appear. The persistence of type, for example, through successive generations for many thousands of years, and the very evident transmission of all physical and psychical characteristics from the male parent to the offspring, how utterly inexplicable upon any gross material theory, when we reflect that from the male parent no

matter passes into the offspring, excepting the fluid contents of a microscopic cell strained through its walls and through the walls of the ovule or ovum! Through this infinitesimal quantity of fluid, filtered through this infinitely close double filter, there passes, in some way, a law of form, and a law of mental and physical idiosyncrasy which is stamped upon the whole terrestrial being of the offspring, bending all the untold energies of gravity and of chemical and electrical attraction, to its own particular whim. Through the whole terrestrial life of the offspring do I say?—yes, and I may include in that word offspring sometimes the whole progeny for a thousand generations. The conscious part of the soul is still less known. Its presence is one of the characteristics of animal as distinguished from vegetable life, and the investigation of its comparative development in different tribes of animals is the most valuable part of the field of natural history.

The soul of the plant is presumed to be unconscious. The phenomena of motion in the sensitive plants, and in the efforts of all plants to throw their leaves to the light and their roots to the richest spots in the soil, are supposed to be as unconscious as the contraction and dilatation of the pupil of the human eye. In that dilatation and contraction there is action adapted instantly to circumstances, and so long as the eye is healthy, with unerring promptitude and accuracy. An observer of the human animal might quote this as evidence of the wisdom of man. But on further thought he might see in the very fact that the action is unerring, evidence that it did not depend on the conscious volition of a finite being. And we, men, know that it is a movement of which we are absolutely unconscious.

In like manner it is presumed by the majority of investigators, that all the movements of plants are made with absolute unconsciousness on the part of the plant, and that plants have in short no consciousness whatever, either of their own existence, or of the existence of a world about them. Now it does not follow that on this account the plant is to be studied in its physical relations alone. It has psychical relations also, of the greatest interest to a true enthusiast in botany. The gardener and the botanist constantly speak of the feelings and tastes of plants, and of their moral qualities—indeed some plants have been named from moral nature, as, for example, Rumex patientia, and Carduus benedictus, the patient dock and the blessed thistle—while others have moral epithets that have become as familiar as their names, as, for example, the modest violet and the flaunting poppy.

The geographical distribution of plants will, I think, be found to depend upon something which eludes our study of the external conditions; something besides that physical struggle for life which the English naturalists see in every part of the animal and vegetable kingdom, as though the poor in those kingdoms were oppressed by unjust and impolitic laws impeding the distribution of land, as they are in the kingdom of Great Britain. There is also what may be called a choice in the plants, not implying by that language any consciousness in the plant, but simply affirming that its flourishing here or perishing there, depends in a great measure upon an idiosyncrasy of constitution, making it sensitive to physical changes that can be measured neither by the thermometer, barometer, hygrometer, electrometer nor chemist's balance. The mayflower of New England, called elsewhere trailing arbutus, will adapt itself, when it chooses, to clay or sand, to deep shaded woods or to sunniest hillsides; and I never saw it so flourishing as once in a peat meadow over which it was slily creeping from a sand bank on its edge. But take the plant up with never so much care, and with never so large a sod of unbroken earth about its root, and transplant it where you will, and it is a hundred to one that it dies in a twelvemonth of a broken heart, pining for its old home. Some of these freaks have been explained by the discovery that some plants are semi-parasitic, stealing from the roots of others a part of their food, and therefore incapable of living except in the presence of their patrons,—but many remain yet unexplained.

It sesms to me, however, very plain that the souls of plants, that which makes the difference between a plant living in the forest, and the specimen in the herbarium, that which guides the forces of nature to the building of the plant, and which turns its leaves to the light, is worthy of study in all its relations. It is a depository of divine thought, deposited there ultimately for our instruction as one of its final causes and therefore worthy of the most careful attention.

The intellectual and moral development of animals is also doubtless governed by a plan. The difference between the dull oyster and intelligent, affectionate dog, is as much the result of a plan, or thought, of the Creator, as is the difference of their forms. The horse and the ox are as admirably adapted to domestication by their mental as by their bodily gifts. All the instincts of all animals are adapted to their organization and to the nature of the world and of other animals among which they are placed.

Even should we suppose that the mental power of animals is the result of their organization, that is to say, even if we should suppose that mental power is latent in matter, and simply rendered active by organization, we should be compelled, upon a thorough study of the mental development of animals, to admit that their souls can be classified upon a logical plan, just as their forms can be; and we should be forced to admit, that this latent soul in matter is capable not only of organizing matter according to a logically developed series of forms, but of eliminating out of its own totality separate minds in a progressive series logically connected.

The very great importance of this study of comparative psychology, of becoming acquainted with the mental and moral characters of animals, is obvious. Many attempts to found a science of comparative psychology have been undertaken. But the field is vast, and the progress of the survey slow. At the Baltimore meeting of the American Association for the advancement of Science, Dr. Weinland proposed a method for this new science, ingenious and sound, but by no means exhaustive. He lays down nine fundamental principles; first, that the distinguishing mark of an animal is its consciousness of an outer world; secondly, that this consciousness of an outer world is the fundamental principle of the soul of animals; thirdly, that the consciousness of self results from and is proportioned to the consciousness of the outer world; fourthly, the degree of psychical development can be judged from the degree of development of the consciousness of an outer world; fifthly, this may be judged from the development of the organs of that consciousness; sixthly, these organs are of three kinds, those receptive of sensations, reflective organs and the organs of voluntary motion; seventhly, we may depend in comparative psychology mainly upon a study of the organs of voluntary motion; eighthly, these motions may be divided into two classes, those which refer only to the animal himself, and those by which he would hold communication with other animals; ninthly, man stands at the head of all animals, since his voluntary motions are not only more numerous and perfect than those of other animals, but because through machinery he increases vastly the number of his organs, runs upon the locomotive, talks through the printing press and telegram, and shows us what is most distant through the telescope and stereoscope.

But it is impossible for us to understand any of the phenomena of consciousness save through an appeal to our own consciousness. The mere investigation of the

organs of an animal and its movements can give no true knowledge of the soul of an animal to one who is incapable of analyzing carefully the phases of his own consciousness; nor would the student who is the most thorough master of the analysis of his own thought and feeling, be able to understand the souls of animals, did not the human spirit contain in itself the germ of every power of every terrestial creature. The disposition to attribute to others and to animals the feelings which we should have, were we in their circumstances, although it may mislead the student both of human and of animal life, is nevertheless an essential to successful study. It is impossible for us to understand beings either higher or lower in the scale than ourselves, except as they in some degree resemble us. Our knowledge of ourselves must keep equal pace with our knowledge of other beings; else we have no knowledge of either.

To recapitulate: In the study of organized beings we find three principal departments, their anatomy, their physiology, and their psychology. Their anatomy deals with their forms, and with the forms of their parts; and these forms furnish in general complete data for their classification. Physiology treats of the peculiarly modified chemical action by which food is assimilated and made part of the living structure, and by which the various secretions are formed. And were not this a much higher and more difficult inquiry than the study of the forms, we might doubtless classify all plants and animals by the chemical likenesses and differences of their tissues and secretions. At present these characteristics are used in classification only as confirmations of the accuracy of the results obtained by form. Psychology deals with the souls of organized beings, with those principles that guide the chemical and mechanical forces in matter to the formation of the organism. The classification of organized beings by their forms is, in fact, in one sense, a classification by their souls by the psychical principles which are empowered to create the forms. But these unconscious souls have other functions than the creation of forms; they have besides this intellectual work, a sort of moral quality by which they select peculiar food and form peculiar products, and by which also they are aquatic or terrestrial, tropical, tender, hardy, arctic or alpine, &c. Then in animals we have, either in the same soul or in a second one, consciousness added to life, the powers of thought and feeling, desire and volition, and of knowing that they think, feel, desire and will, and these powers culminate on earth in the human race.

Matter is a storehouse of forces; in each atom slumber or rage the forces of attraction and repulsion, and also the moral qualities of chemical difference and identity. These forces, whether chemical or mechanical, act according to fixed laws, and tend towards a state of rest and of stable equilibrium. And they are all so correlated that each of them can be referred as forces, to one common unit, and shown to be capable of lifting such a weight so many feet a second.

But organized beings push always into motion, and their tissues and secretions are usually such that, in air of the same temperature and moisture as that in which they grew, they will rapidly decay the moment that life is gone. They are perhaps in chemical equilibrium; but it can hardly be called stable,—at least it is not stable enough to resist the very heat and atmospheric influences under which it was built. Yet there is no trace of any force in the organism thus compelling the forces of inorganic matter to act in this peculiar way, so different from their behavior when the organizing life is wanting.

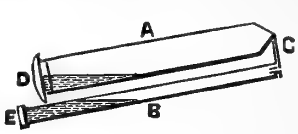
The intellectual power of the unconscious soul is not a force that can be compared with gravity, it cannot be measured by that unit; it does not act by attraction and repulsion, but simply guides (we know not how) the forces which do thus act—it rules them by moral or intellectual, not by corporeal power. The souls of plants and animals have a certain lordship over the earth, and the earth obeys their rule to a certain extent. This lordship is exercised in part involuntarily and unconsciously, that is in the phenomena of nutrition and growth; and in part consciously, in the phenomena of voluntary thought and motion and action. And had we sufficient knowledge of the habits of animals, we could doubtless classify them according to their voluntary life.

But in classifying organized beings, we do not find ourselves imposing law upon the series of species, but discover it already impressed upon them. Not only does the soul of the single organism develop thought, but in the whole gradations of the universe, from the chemical atoms up to the highest orders of mammalia, we find the development of more extensive thoughts; as though the whole universe had a soul; developing it as the soul of the violet develops its forms and color and odor. Now does this soul of the universe act consciously or unconsciously? Shall we take the vegetative power, or the conscious mind, as the type of the Deity? In endeavoring to find a symbol for the Highest in the universe, shall we look for the light of analogy into what is highest in ourselves, the conscious soul? or into what we have in common with the seaweed, the organizing power of life?

To me the answer is evident, that the highest of which we are conscious is the best symbol by which to speak of the Highest who is above our consciousness. Looking thus at the Divine Being as the Lord, who has consciously expressed His thoughts in the material world, that world becomes glorified and glows with heavenly splendor. Natural science becomes the study of the autograph works of an Infinite Author; and natural history—which is the highest of the series of physical sciences, and links them to the sciences that deal with the human mind and the works of man—becomes the means of communion with the highest geometrical, algebraical and chemical thought, which the Father of men has as yet revealed to us; and also becomes through the study of the instincts and reason of animals the fittest of all natural preparations for a study of ourselves, and of our own relations to the All wise and All good.

SIR W. THOMSON'S NEW DEPTH GAUGE.

Sir William Thomson has very recently patented another depth gauge which, though it depends upon capillary action, does not require the co-operation of chemical change. In fact, it operates by capillary action alone. The accompanying figure will illustrate the principle of this new device. Here A and B are two



glass tubes of different diameters united by a capillary tube C. The narrower tube, B, is closed at the end by a plug E, which can be removed at will: and the wider tube A is covered by a sheet of cotton cloth. This cloth acts as a porous septum which, when wetted, is permeable by water but impervious to air. For according to a law of hydrostatics, a film of water in a hole resists a difference of air pressure on its two sides, equal to the hydrostatic pressure due to a column of water in a capillary tube of the same diameter as the narrowest part of the hole. Thus it is that damp linen is impervious to air, and wet sails resist the wind much better than dry ones, as every sailor knows.

When this arrangement is lowered into the sea, water forces its way into the tube E, and the quantity forced into it during the descent becomes an indication of the depth when the relative capacities of the tubes are properly adjusted. In raising tne apparatus the water

in the wide tube is gradually expelled by the air, and the wet cloth secures that all of it will be driven out before any air gets in. The water contained in the narrower tube remains to indicate the depth by a suitable scale engraved on the glass, and then is let out by withdrawing the terminal plug.

For actual use the wide inlet tube is made of brass and the narrower tube of glass. Three sets of these tubes are combined into one instrument, and in each set there is a special ratio between the capacities of the inlet and retaining tubes, in order that the set in question may answer for certain depths. Flying soundings are usually taken in depths ranging up to 130 fathoms, and the three sets are designed to indicate depths, say, from 12 to 28 fathoms, from 28 to 60 fathoms, from 60 to 130 fathoms. They are fitted into a brass protecting cylinder, open at one end to the water, and slotted out in the sides to allow the engraved scales on the gauge tubes to be seen from the outside. The whole is then enclosed in a galvanized iron guard-case drilled with small holes to allow the sea-water to enter, and being attached to the sinker is lowered into the sea. The apparatus is manufactured by Mr. Whight, of Glasgow, for Sir William Thomson, and it has already been adopted on H. M. S *Valorous*, and the Russian imperial yacht *Livadia*.

While upon this subject we may also draw attention to the "nipper" lead of Mr. Lucas, engineer to the Telegraph Construction and Maintenance Company. The old plan of ascertaining the nature of the sea bottom, by bringing up a specimen of it in a tube, let into the bottom of the sinker and armed with tallow, is open to several objections. For instance, the specimen is apt to get washed out in rising to the surface, and when it is safely brought on board it is usually so smeared with tallow as to be objectionable. The nipper lead of Mr. Lucas, on the other hand, retains what it catches and renders it up in a pure state well fitted for preservation. The bottom of the lead or sinker in question is provided with two hollow claws or spoons, not unlike the mandibles of a crab. These are hinged to the sinker, and open out against the resistance of a stout spiral spring which is contained in the body of the sinker. When fully opened out they are kept apart by a locking device, consisting of two crossbars which meet end to end and fit into each other. The points of the open claws, however, in striking upon the bottom, spring this lock, and the claws snap together with great force, nipping up a specimen of the bottom at the same time, and from their hollow shape this specimen is retained. So effective is the nipper lead that the claws will nip a sheet of paper off a table, and they have been found to raise a specimen of the bottom from 2,000 fathoms.—*Engineering*.

BOTANICAL NOTES.

Every young naturalist needs to be on his guard against deception which is a frequent cause of serious mistakes.

Many strange species and unheard of peculiarities are sometimes discovered by the over zealous and credulous. Most imitations of natural objects are so bungling as to be readily detected, but occasionally something turns up which is such a surprise, that the fact is noted before its improbability is made evident.

The large springs of the limestone districts of Pennsylvania are exceedingly clear, cool and transparent. The principal plants living in them are species of Characeæ, and Veronica Americana, whose large, lettuce-like leaves have a very striking appearance when seen through the sparkling water. While visiting a spring one day in mid-summer, I was surprised to see some strange looking plants which appeared to be Marata cotula. Mentally noting this peculiar position for such a common and well-known weed of dry ground, I caught sight of something still stranger—a garden aster; another step and a zinnia and dahlia came to view. Indeed there was quite a garden "á immersion."

The small boys of the neighborhood had acquired the art of deftly binding flowering branches to small stones which held the plants to the bottom, while the strong upward flow of the water kept them neatly upright and life-like.

The search for plants upon vacant city lots, rubbish piles, and the like, always reveals a greater number and variety of species than one would suppose.

As several of these "local" floras have been published lately, I give one which interested me a good deal at the time of noting it. In Kingsford's Oswego Starch factory, large quantities of lime are used in the manufacture of corn starch. The refuse lime is a pasty mass still having to a considerable degree the caustic properties of fresh lime. Large quantities of it accumulate about the factory, and are hauled off to get it out of the way. Several hundred loads were once deposited in the middle of a pasture, in a loose pile varying from three to six feet in thickness. Cattle tramped over it carrying more or less mud upon their hoofs, and their droppings collected to a considerable extent upon it. In time plants began to get a foothold there, and one mild day in winter, about three or four years afterward, I visited it, and was surprised to find the following well established: Cirsium, 2 sp., Rumex, Poa, Phleum, Plantago, Graphalium, Verbena, Trifolium, 2 sp., Solidago, Marata, Chenopodium, Polygonum.

The white clover was especially luxuriant, and covered patches of several square feet with a perfect turf.

W. A. B.

A popular work on Algæ, by Rev. A. B. Hervey, to be illustrated with colored plates, is announced.

Professor Alphonso Wood, widely known as the author of a Class-book of Botany and other botanical text-books, died at his residence at West Farms, New York, on the 4th inst.

Trimen's *Journal of Botany*, despite its long standing and being without a rival in its chosen field, is obliged to make a call for a more liberal support in both subscriptions and contributions. This does not speak well for the enthusiasm of English systematists.

The second volume of *The Botany of California* has made its appearance. It includes the remainder of the Phanerogams not treated in Vol. I., the Pteridophytes, and the Mosses, and brings this eminent work to a successful close.

A new manual of the mosses of the United States will be published during the present year. The authors, Leo Lesquereux and Thomas P. James, are the most able and distinguished bryologists of America. The edition will not be large, and for the present the price is fixed by the publishers at $3.00. Such a manual has been needed for a long time.

In *The American Naturalist* for January, Professor Bessey calls attention to the Fly Fungi belonging to the genus *Entomophthora*. They have been but little studied. The most common species (*E. muscæ, Fres.*) infests the house fly. Dead flies are common in autumn covered with a white powder which fastens them to the walls and other objects of the room. Upon examination the bodies are found to be filled with the mycelium of the asexual stage of the fungus, the white powder being the conidial spores. This asexual form is described in many books under the name *Empusa*. The sexual stage developes entirely within the host, filling it with a mass of oöspores and hyphæ. The genus *Tarichium* is founded on this sexual condition of the plant. The two genera Empusa and Tarichium not being antonomous are re-

placed by the genus Entomophthora; but it is proposed by Giard, who has investigated the subject recently, to retain these names to designate the asexual and sexual stages respectively. These plants belong to the interesting order *Saprolegniaceæ*. Other species of the same order are abundant on dead and living fish, cray-fish, etc. They have sometimes proved very destructive to the young fish in hatcheries. The species of the order are not well known, although examples are easily obtained.

J. C. A.

MICROSCOPY.

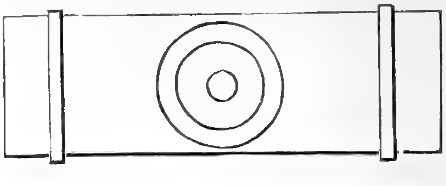
Mr. Julien Derby recently read before the Quekett Microscopical Club a paper describing various special "dodges," which may be employed by microscopists to facilitate their researches.

I. When allowing all but adepts in the use of microscope to peep through my high power glasses, I have often felt a certain degree of uneasiness, not to say of alarm, regarding the fate of valuable test-slides, or still more valuable objectives. Many others here present have no doubt experienced the same discomfort which I find an easy matter to attenuate to a considerable extent, by focussing from the eyepiece instead of from the coarse or the slow motion. All that is needed for this is a rack and pinion to the eyepiece of considerable length. An inch or two up or down corresponds here to a fraction of a turn of the fine adjustment of the microscope, so that very little danger exists of any sudden contact with the covering glass. As soon as an indistinct view of the object is obtained through the ordinary coarse adjustment of the microscope body, the focus is brought to exactness by means of the coarse motion of the eyepiece without much difficulty. For demonstrations or exhibitions in public, microscopes could thus be made without the ordinary fine motion.

II. When mapping with micro-spectroscope, the difficulty of measuring exactly the position of fine lines or absorption bands is often great, even when using the admirable micrometers invented by Mr. Browning and Mr. Sorby. I find that in most practical cases the micro-spectrum can be thrown upon a sheet of white paper by means of an ordinary camera lucida placed over the eyepiece of the spectroscope. Strong light by means of a condenser has to be thrown through the liquid under examination. By means of an ivory rule, finely divided, and brought back to a known line, say D, all other lines or bands may be directly measured off on the rule, and, if desired, the exact results in millionths of a millimetre may then be computed by any of the known interpolation formulæ, such as are given in Suffolk's useful little book.

III. The arrangement of small microscopic objects, such as diatomis, foraminiferæ, etc., on slides in regular lines, circles or patterns, can be much facilitated in the following way: "Draw with a pen and ink cross lines, or circles, or any other figure required on the surface of the plain mirror of the microscope; then focus down until the image of these lines is seen on the upper surface of the top lens of the condenser. By means of a mechanical finger, or of a steady hand with a rest, no difficulty will now be experienced in placing the objects in perfectly regular order.

IV. I now obtain excellent condensed monochromatic light by means of a bull's eye of unusual external shape, the internal portion of which, however, is filled with glycerine or oil of cloves colored to suit. This bull's eye has a plane back and a concavo-convex front, and the liquid is introduced through a hole in the flat side, closed by a small ground stopper. This apparatus is furnished with universal motions, and has a rack and pinion foot. It was made for me by Mr. J. Browning. When using blue light, produced by ammonia sulphate solutions, I have resolved, by means of this monochromatic bull's-eye amphipleura, with objectives in my possession, which will hardly show *Pl urosigma angulatum* under ordinary condenser illumination.



V. Some time ago, Mr. J. E. Ingpen, on my behalf, made a communication to the Club in regard to a growing regard to a growing slide I had devised for some special researches I was following at the time. Some difficulty seems to have been found in the making of these slides, so that it is with pleasure I now offer a still more simple contrivance for obtaining the same results. Here is the receipt: Take an ordinary glass slip with a circular hole, say, half an inch or more in diameter in the middle; lay this slip on an ordinary glass slide, not perforated. Then grease the top of the upper or perforated slide just a little way around the circular hole, and join the two slips of glass by means of two rubber rings (see Fig.). The object is then placed on a thin cover-glass, somewhat larger than the hole in the slide: it is covered by a thin glass cover, ¼ in. in diameter; the whole is then turned down and fastened to the slide by the adherence with the grease, while the small cover prevents the running of the liquid. The plant or animal under examination finds itself confined in a sort of minature Ward's case. When not under observation, the growing slide is laid flat in a shallow plate with water just above the line of junction of the two slips of glass, where, by capillarity, it creeps up to the central cell, where evaporation keeps the contained atmosphere in a state of constant and healthy saturation.

VI. *Copal Varnish*. I find this varnish dries very rapidly if slightly heated, or even if placed on a previously warmed slide. I have many hundred slides of diatoms prepared in copal varnish, and my friend, Mr. Van Heurck, of Antwerp, who was the first to use this material, has many thousands. The varnish to be used is what is called the "pale copal," and its consistency ought to be that of oil. It is much pleasanter to use than Canada balsam, does not make bubbles, and its refractive index is not very different from that of balsam, and does not interfere with the solution of diatom markings. I have of late made many preparations in copal, dispensing with the cover-glass altogether. The drop of copal is placed on the diatoms and heated lightly over the spirit-lamp. It soon takes the consistency of amber, and is hard enough to sustain wiping and brushing with a soft brush with impunity. The optical aberrations produced by the cover-glass are thus done away with.

ASTRONOMICAL MEMORANDA.

Professor C. A. Young has examined the 70 lines given on Angström's chart as common to two or more substances. Of these 70 lines, 56 were seen distinctly double, or triple; 7 single; and in regard to the remaining 7 there is still an uncertainty. The instrument used was a diffraction spectroscope with collimator and observing telescope, each of 3-inch aperture and about 42 inches focal length, and a Rutherford grating of 17,300 lines to the inch. The apparatus was strapped to a 12-foot equatorial provided with a driving clock, and powers magnifying from 50 to 200 diameters were used. A large prism with a refracting angle of 20° was placed between the object glass of the

equatorial and the sun to throw out the parts of the spectrum not under examination, and a concave cylindrical lens was used next the eye to reduce the apparent width of the spectrum, and thus increase its brightness.

From Professor Young's observations it thus appears that the coincidences are only near approximations, but a careful investigation by bringing together the bright-line spectra of the metals and the solar spectrum must be made in order to settle the question conclusively.

Mr. E. J. Stone has presented to the Royal Astronomical Society the complete sheets of his great Catalogue of Southern Stars, observed during his superintendence of the Royal Observatory, Cape of Good Hope. This very important work contains the places of between twelve and thirteen thousand stars, including, in addition to the stars observed by Lacaille, a considerable number of stars falling within similar limits of magnitude. "A stereographic projection showing the distribution of the stars contained in the Cape Catalogue, 1880, between 110° and 180° N. P. D.," has been lithographed by Mr. Stone.—*Nature.*

W. C. W.

As noted in the issue of last week, the volume of reports on the total eclipse of 1878, has been recently issued from the Naval Observatory at Washington. A few separate copies of the report of Mr. D. P. Todd, assistant in the office of the American Ephemeris and Nautical Almanac, have been reprinted, mainly for distribution among the gentlemen who co-operated in observing the duration of totality along the limits of total eclipse. Besides the usual observations of contacts, Mr. Todd had planned a search for supposed intra-mercurial planets, having provided himself with the four-inch comet seeker belonging to the Naval Observatory. At his station, however (Dallas, Texas), clouds intervened to such an extent that δ Cancri, a fourth magnitude star near the sun, could not be seen. This station was almost the only one of any importance at which clouds interfered on the day of the eclipse. Mr. Todd describes in his report a new method of procedure in the observation of total eclipses, whereby it would seem that the question of the existence of intra-mercurial planets might be speedily settled. An arrangement was concluded between Professor Newcomb (observing in Wyoming), and himself, whereby, if the former should observe any such object, its approximate position should be telegraphed immediately to the southern station for verification—there being about twenty minutes of absolute time intervening the arrival of of the moon's shadow at Wyoming and its reaching Texas. As Professor Newcomb observed no unknown object, there was, of course, no occasion for carrying out this scheme; but it will readily appear that, had the weather been clear at the southern station, and had the position of the objects seen by Professor Watson, been telegraphed for verification, the question of small planets near the sun might have been in a much less uncertain condition than it now is. It is to be hoped that astronomers may utilize this scheme on the occasion of the next total eclipse on the 16th of May, of next year. Eleven sketches and one lithograph plate of the corona accompany this report, but they do not exhibit any details of structure worthy of note. But by far the most importantant portion of Mr. Todd's report relates to the observations of duration of totality, which were made at his solicitation at numerous points along the northeast and southwest limits of total phase. This series of observations will afford a very accurate correction of the longitud of the node of the lunar orbit, whenever the geographical positions of the several stations have been determined with sufficient accuracy to be used in the computation.

NOTE ON SUN SPOTS IN JANUARY, 1881.

To the Editor of "SCIENCE:"

1st, at noon: 5 groups, 11 spots. One spot quite large and close to east edge. Air very tremulous, making observation bad.

7th, 3 P. M.: 1 group, 3 spots. Two are large; nearly north of centre. Air bad. Observation with spyglass, power 36.

8th, 1 P. M.: 1 group, 4 spots. Air very bad.

10th, Noon: 1 group, 6 spots. Air very bad. Power 50.

11th, 2½ P. M.: 2 groups, 9 spots. One group of 7 spots 3' from west edge. Two little spots and faculæ at east edge. Air pretty good.

17th, Noon: 1 group, 2 spots. A large spot near halfway from centre to N. W. margin. Observation with spyglass, power 36.

24th, 10½ A. M.: 3 groups, 23 spots. 12 spots, 2 quite large, south of centre. Air poor.

18th, Noon; 5 groups, 66 spots. One quite large and 5 good size, near west edge. Only good observation this month. The sun was hid most of the time.

Telescope 4.6 inches aperture; Power 100, except otherwise noted.

The number of solar spots has been slowly increasing since March, 1879. But it looks likely that the next maximum will be considerably more than eleven years from the last one, which occurred about August, 1870. The following minimum was nearly nine years afterward. It is generally about seven years from maximum to minimum, then four years to the next maximum. So I think it probable that the period, this time, will be about thirteen years, making the next maximum in 1883.

WM. DAWSON.

SPICELAND, IND., February 2, 1881.

CHEMICAL NOTES.

FORMATION OF BASES FROM SUBSTITUTED ACID AMIDES.—O. Wallach and Iwan Kamenski conclude, from their experiments, that if a base is formed by the action of phosphorous penta-chloride from a substituted amide of monobasic acids with a short carbon chain, two molecules of the amide enter into reaction in such a manner that hydrogen is derived from the hydrocarbon radicle pertaining to the acid in order to form hydrochloric acid.

ZINC CHLORIDE AS A REAGENT FOR ALKALOIDS, GLYCOSIDES, ETC.—A. Jorissen has found that the following bodies produce characteristic reactions with pure zinc chloride: Strychnine, bright rose; thebaine, yellow narceine, olive-green, delphinine, brownish red, berberine, yellow; veratrine, red; quinine, pale green; digitaline, chesnut-brown, salicine, violet-red; santonine, violet-blue; cubebine, carmine red. In case of strychnine the reaction can be produced with 1 decimilligrm. of the hydrochlorate. Brucine and aconitine, if present, interfere. To obtain the blue coloration characteristic of santonine, the mixture during evaporation must be continually stirred with a glass rod drawn out to a point. Digitaline gives first a green solution, similar to that produced by heating with hydrochloric acid. After evaporation there remains upon the porcelain a chestnut-brown spot which quickly blackens. The salicine reaction can be used for detecting the fraudulent addition of this body to quinine sulphate. Albumenoid substances, if heated for a time with the zinc chloride solution, leave a violet stain upon the porcelain, which may be distinguished by its instability from the colorations mentioned above. As a rule it quickly blackens. The author's method of operating is as follows: A solution of the alkaloid or its hydrochlorate is evaporated to dryness upon the water-bath, say in the inside of the lid of a porcelain crucible; two or three drops of the test-solution—1 grm. fused zinc chloride in 30 c.c. concentrated hydrochloric acid and 30 c.c. water—are placed upon the residue, and dried up afresh on the water-bath. The coloration begins at the outer edge and spreads inwards as the water is expelled.

BOOKS RECEIVED.

ON CERTAIN CONDITIONS OF NERVOUS DERANGEMENT. By William A. Hammond, M.D. Published by G. P. Putnam's Sons, 182 Fifth Avenue, New York, 1881.

The recent lecture of Dr. Beard before the New York Academy of Sciences, on "Mesmeric Trance," appears to have revived an interest in this subject, and new works bearing on Hypnotism are promised by those who have of late given attention to the phenomena in question.

The work before us by Dr. Hammond, therefore, comes at an opportune moment, for it not only explains very fully the author's views on "Hypnotism," but all the other conditions of nervous derangement which are evidently allied to the same class of mental disturbances. Thus we have chapters on Somnambulism, natural and artificial, including Hypnotism, various phases of Hysteria, the Hysteroid Affections, Stigmatization, Supernatural cures. Some of the causes which lead to sensorial deception and delusional beliefs.

Although the present work is a reprint of a previous book published by the author in 1876, Dr. Hammond states that he has thoroughly revised, and added largely to the subjects now considered, and also "omitted every thing specially relating to spiritualism."

Turning to the subject of Hypnotism, we are somewhat surprised to find it classed under the heading of Artificial Somnambulism, especially as we understood Dr. Hammond to state in a recent lecture before the University of the city of New York, that he attributed the phenomena to quite another cause, and for this reason he proposed to dispense with the term Hypnotism, which implies "sleep," and suggested the introduction of the word "Syggnosticism," meaning union of thought, or sympathy of thinking between two persons. The subject is also complicated by finding two such authorities as Dr. Hammond and Dr. Beard giving conflicting explanations of the phenomena.

Studying the one case of Hypnotism given by Dr. Hammond as the result of his experience, it appears to come to any other conclusion than that the phenomena presented in Hypnotism are merely manifestations of disease.

The instance we refer to was that of a young lady of great personal attractions, who up to a certain time was in a normal condition.

We first find that her nervous organization became depressed and demoralized by a great domestic bereavement, and further prostrated by fatigue, excitement and grief. The trouble commences by the young lady showing symptoms of chorea, the muscles of the face being in almost constant motion. The next step was that she talked in her sleep, and later she walked in her sleep and became a confirmed somnambulist. In the latter condition she walked about the house, struck a match and lighted the gas, seated herself in a chair and looked fixedly at the portrait of her lost mother.

While gazing at the picture she was subjected to various experiments by Dr. Hammond, her olfactory nerves received no impression from the fumes of sulphurous acid gas; she failed to perceive the sour taste of lemons or the bitter taste of quinine; scratching the back of her hand with a pin, pulling her hair and pinching her face appeared to excite no sensation, thus exhibiting all the phenomena of Hypnotism.

The next stage of this case develops a power in the patient of inducing the hypnotic state at will. Her process was to fix her attentions by reading a book and fixing her eyes steadily to reflect as if in a reverie, when she would presently pass to a perfect hypnotic condition.

Without professing to give a final opinion on the phenomena of Hypnotism, we direct attention to this authentic case presented by Dr. Hammond as showing what appears to be the evolution of Hyprotism.

First we find the subject in health, with all the functions and conditions of life normal. Secondly, the body and nervous organization is subjected to a great mental strain, developing a modified Hypnotic condiition. Thirdly, the disease becomes chronic and all the phenomena of Hypnotism are established and the patient is subject to hysteria, catalepsy and ecstasy, three conditions Dr. Hammond considers present in confirmed Hypnotism. There must be a final stage, the form of which may depend on circumstances. Under judicious treatment perhaps a normal condition of the nervous system may be restored, while, on the contrary, a further development of the disease may result in a total breaking up of the nervous system, followed by mania.

These reflections are suggested by the work before us, but in the present condition of the question it is impossible to arrive at any satisfactory conclusion. Drs. Hammond and Beard are not agreed even on the fundamental principles involved, and the former employs two terms for the phenomena, which are antagonistical to each other. It is therefore evident that ample opportunity is presented for a more thorough examination of the question, the result of which would doubtless improve our knowledge of mental diseases, many of which are at present inexplicable.

PAPILIO.—Devoted to Lepidoptera exclusively.—Vol. 1, No. 1, January, 1881.—Mr. Henry Edwards, No. 185 East 116th street, New York City.

This Journal is the authorized organ of the New York Entomological Club, and will be issued about the fifteenth of each month (excepting the two mid-summer months) the subscription being $2 per annum.

The first number contains many articles of interest to entomologists, and a full-page colored illustration of the beautiful insect Edwardsia brillians, from a specimen captured in N. W. Texas by the late Jacob Boll.

Entomologists will welcome this Journal, which in the hands of Mr. Henry Edwards will, doubtless, be maintained at a high standard, aod command success.

USE OF GLASS-WOOL IN FILTRATION.—F. Stolba and R. Böttger. Both these authors point out that glass-wool is attacked by various liquids, including hot water.

DETECTION OF PRE-FORMED UROBILINE IN URINE.—One hundred c.c. of urine are gently shaken up with 50 c.c. of perfectly pure ether; the ether decanted off and evaporated. The residue is taken up in absolute alcohol, and is rose-colored with a green fluorescence. The experiment does not always succeed.—E. SALKOWSKI.

A COLORING MATTER FROM CARBON DISULPHIDE.—If carbon disulphide is agitated with semi-fluid sodium amalgam, and if the paste-like mass is mixed with water, there is produced a hyacinth red liquid, whilst mercury and mercury sulphide are deposited. The solution contains the sodium salt of a yet unknown acid, somewhat soluble in hot water, and more readily in alcohol. It dyes yellow, orange, and brown shades on wool and silk.—C. REICHL.—*Polyt. Notizblatt*, 35, 151.

HOMOFLUORESCEINE: A NEW COLORING MATTER FROM ORCINE AND ITS DERIVATIVES.—On heating solutions of orcine with caustic alkalies and chloroform, the liquid becomes purple and then fiery red, and on dilution shows a strong greenish yellow fluorescence. This reaction is exceedingly sensitive. On neutralizing and adding bromine water a compound is formed from the fluorescent coloring matter resembling eosine; its alkaline alcoholic solutions appear cherry-red by transmitted light with yellow fluorescence. Though many of these compounds have splendid colors, only the nitro-derivatives are suitable for dyeing. Hexa-nitro-mono-oxy-homo-fluoresceine dyes silk a brilliant orange, the penta-nitro-diazo-amido-monoxy-homo-fluoresceine compounds a gold yellow and cyamic acid a light reddish yellow.—H. SCHWARZ.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, FEBRUARY 19, 1881.

PROFESSOR WATSON'S SUCCESSOR.

Prof. E. S. Holden, U. S. N., has been detached from the Naval Observatory, and granted a year's leave of absence, in order to take charge of the Washburn Observatory, of the University of Wisconsin.

The sudden death of Prof. Watson left his plans in a very unfinished state. He had partially completed, at his own expense, a "solar observatory" which bears his name. His plan was new, and he intended to re-discover the intramercurial planet, Vulcan, which he reported during the total eclipse of 1878. At the bottom of a hill, sloping at an angle of about forty-five degrees, a small building with a deep cellar was built. A tunnel about eighteen inches in diameter and fifty-five feet long, parallel to the earth's axis, connects this cellar with a pier at the top of the hill which is to support a heliostat. As the tube is pointed directly towards the north pole, it is necessary to give the heliostat but one motion in order to keep the sun in the field of view of the observing telescope placed in the cellar at the bottom of the hill. The object of the long tube was to cut off as much of the stray light as possible, and to enable the observer to examine objects close to the sun's limb.

The Washburn Observatory is provided with an excellent 16-inch Clark equatorial, which is ready for work. Fauth & Co., of Washington, are making a good 3-inch transit instrument, similar to that of the Princeton College Observatory, and it is probable that later a 6-inch meridian circle will be ordered from Repsolds, of Hamburg.

The work to be carried on for the coming year consists, mainly, of a systematic review of the heavens, following up Herschel's work. It is probable that this work will be done by Professor Holden and Mr. S. W. Burnham, in concert. The transit instrument will be used by Mr. G. C. Comstock in maintaining a time-service, and incidentally in obtaining a set of Right Ascensions of the sun, and an extended series of observations of Polaris.

The State of Wisconsin has provided for the printing of the publications of the Observatory. The volumes will be issued at irregular intervals. No. I. will be a History of the Observatory under Prof. Watson's administration, together with the reduction tables prepared by his directions, and No. II. will probably contain Burnham's General Catalogue of Double Stars for 1880.

It is said that during the memorable battle of Waterloo, competent judges pronounced Wellington more than once a defeated general, and that, according to the rules of war, he should have retreated on Brussels. But Napoleon looked in vain from La Belle Alliance to see his foes fleeing before him, for Wellington had given the order "*stand fast, we must not be beaten*," and in a few hours he was marching victoriously on the road to Paris.

During the last twelve months we have heard much of another man, who was supposed to be defeated in every point, and was reported by the English scientific press to have abandoned the battle field at Menlo Park, and to be slowly retiring on California. Professional men and others, who accepted such views on the subject, have from time to time, with a persistence worthy of a better cause, proclaimed aloud that Edison was beaten, and that, in their opinion, his whole system of electrical lighting must end in failure.

But Edison, like Wellington, in the midst of many difficulties, merely closed up his ranks and gave the order "*we must not be beaten!*" The historical parallel may be carried further; Edison may be said to have marched on Paris, and entered the enemy's Capitol, for having accomplished his task at Menlo Park, and perfected his system of electric lighting in all its details with the most perfect success, we now find him installed in sumptuous offices in Fifth avenue, New York city, putting into practical operation the full results of his previous experiments.

A company has been formed which will control and place Edison's system of electrical lighting on the market, but "the Master" will himself superintend all the details of the construction department, until a district has been finally laid out and found to be working satisfactorily. Progress has been made in this direction, and the Edison lamps are being placed in position as fast as they can be produced at Menlo Park, under the direction of Mr. Upton.

Taking a retrospective view of the last eighteen months, one may well pause to ponder over the immense amount of work accomplished by Edison during

that period. Scientific investigations of the most complicated nature have been successfully carried on, the ordinary beaten paths of research of the Chemist, the Engineer and the Electrician have been cast aside, and original methods of exploring the whole domain of science employed with indefatigable perseverance. The very text books and scientific literature on which others have relied, proving unreliable, were rejected, and Nature, at its fountain head, consulted in solving the these problems.

With such methods and indomitable will, and with the constant and valued co-operation of Mr. Charles Batchelor and Mr. Francis R. Upton, the great work has been successfully accomplished.

The arrival of Edison in New York with his corps of skilled electricians and engineers, occurs at an opportune moment. Deaths from suffocation caused by the escape of the ordinary illuminating gas have multiplied of late, and as we now write the bodies of two women who have died from this cause, await burial. During the last few days a building on Broadway suffered from a violent explosion of illuminating gas, making the second within a few weeks. In the first instance many persons were injured, and in the more recent case one hundred persons escaped death only by the force of the explosion taking a fortunate direction. With the acceptance of Edison's system of electric illumination, these dangers to health and life, to which we have been so long exposed, become as things of the past, except where voluntarily encountered, and to this extent Edison may claim to have conferred a benefit to which the whole world will be heir.

We are under obligations to the Marchioness Lanza for a fine translation of a paper by the renowned Professor Rudolph Virchow, of Berlin, entitled "*Organic Healing Power.*" This paper, involving many points of general scientific interest, will be produced in our next issue.

Virchow is now in his 61st year, and it is 36 years since he was challenged by Count Von Bismarck to fight a duel, on account of Virchow (who was an advanced liberal) having defeated Bismarck's project to obtain money from the Parliament to create a German navy.

AMERICAN CHEMICAL SOCIETY.

The February meeting of the American Chemical Society was held on Friday evening, February 11, 1881. The meeting was called to order by Vice-President Leeds, after which the following gentlemen were duly elected members of the society, viz.: Messrs. N. Gerber, James F. Slade, Theodore M. Hopkey, Professor F. N. Venable, and E. K. Dunham. Dr. E. R. Squibb then took the chair and Professor A. R. Leeds read the following papers:

I. Upon the invariable production, not only of ozone and hydrogen peroxide, but also of ammonium nitrate in the ozonation of purified air by moist phosphorous.

II. Upon the action of ozone, oxygen and nascent oxygen upon benzine.

III. On a new class of aromatic sulphurous acids.

Mr. J. H. Stebbins, Jr., followed with some remarks on tetra-azo-compounds, substances to which he has paid particular attention, for it will be recollected that a whole series of the di-azo-colors were originally produced by him.

Professor W. G. Levison then gave the Society the results of some recent experiments by him on polarized light. On the conclusion of this paper, the society was adjourned. M. B.

New York, February 17, 1881.

NEW YORK MICROSCOPICAL SOCIETY.

The third annual reception of the New York Microscopical Society was held on February 14th, 1881, at the rooms of the Academy of Sciences. The annual address of the President was delivered by Professor R. Hitchcock, who selected as his subject: "The Relations of Science to Modern Thought," on the conclusion of which the meeting resolved into a *conversazione*, when a variety of interesting but familiar objects were exhibited.

THE annual meeting of the German Chemical Society took place December 22, 1880, on which occasion the following officers were elected for the present year: President, A. Baeyer; Vice-Presidents, A. W. Hofmann, L. v. Barth, F. Hoppe-Seyler, H. Landolt; Secretaries, F. Tieman, A. Pinner; Vice-Secretaries, E. Bauman, Eug. Sell; Treasurer, J. F. Holtze; Librarian, S. Gabriel. M. B.

THE SOCIETY OF TELEGRAPH ENGINEERS, (England).

On Wednesday, last week, Prof. G. C. Foster, F. R. S., president, read his inaugural address before the Society of Telegraph Engineers and Electricians, the principal thing dwelt upon being the practical importance of a trustworthy system of electrical measurements. The Society, he said, was not merely a professional one, but was concerned with the scientific principles which underlie the practical operations of electricity. The present practical applications of electricity owed their existence to scientific discoveries made just over 60 years ago. Reference was made to the investigations of Oersted in 1820, and Davy in 1821. Induced electrical currents enabled the electric light to cease to be a scientific marvel and become of practical interest to municipal corporations and limited liability companies. Davy first produced an electric light by the passage of currents from a battery of 2000 cells between carbon points. Oersted, Ampère, and Faraday traced out the fundamental laws of the phenomena of induction. In the ordinary course of scientific discovery, the qualitative aspects of phenomena first attracted attention. Quantitative knowledge followed later by degrees. "Absolute values of constants" could only be given when a phenomenon was sufficiently well known for its laws to be expressed in definite mathematical formulæ, or when methods for the determination of such values could be devised. But when definite results had to be produced as part of a commercial undertaking, that point became of the utmost importance from the very first. Examples were given. During the past 100 years an unknown large number of electrical machines had been made for more or less scientific purposes; but after all that experience it was a question as to who could draw up a specification for an electrical machine which should, with a given number of revolu-

tions, produce a known quantity of electricity, or which would charge a condenser of one microfarad capacity to a given potential. Knowledge as to the power of a galvanic battery was much more definite. Everything in that respect could be stated with exactitude. If knowledge of the practical uses of electrical machines were comparable with that in respect to the galvanic battery, knowledge as to the efficiency of the former would soon be equally definite. The necessity of proper standards based on numerical data was understood in more than one branch of physics; but the present remarks were directed only to electricity, which had in recent years undergone almost a complete transformation. After describing the principles upon which a system of electrical measurement should be founded, the steps taken by Ohm, Weber, Oersted, and others, in arriving at definite laws, were related and tabulated for comparison. Weber's system had been extended by Sir W. Thomson, and the practical applications of electricity in its early days produced the necessity of being able to express results upon a coherent system of standard units. For that purpose the committee of the British Association on electrical standards was appointed, and the B. A. unit resulted. The data upon which that unit was founded had subsequently been verified, and at the present time a redetermination of its accuracy was about to take place. The absence of any standard resistance coils was pointed out, and the suggestion made that it would reflect credit on the Society if it at once set to work with the view of establishing a definite standard resistance, with which instruments used for every-day practical purposes could be occasionally verified and adjusted. A paper on "Some Experiments on Induction with the Telephone," by Mr. A. W. Heaviside, was then read. In the discussion which followed, Prof. Hughes, Mr. Stroh, Prof. Ayrton, and others took part.

FURTHER NOTES ON THE BRAIN OF THE IGUANA AND OTHER SAUROPSIDÆ.

By Edward C. Spitzka, M. D.

I would add to the observations published in No. 7, Vol. I. of Science, relating to the brain of the Iguana, the following:

1st. The ganglionic intumescence upon the inner edge of the cerebral hemisphere, which I supposed to represent the homologue of the molecular basis of the Fascia dentata of Tarini in the mammalia, is more voluminous in the middle of the hemispheric length, than in the posterior third. The homologization of the entire inner wall of the hemisphere with the *Cornu Ammonis* of mammals gains strength from the fact that in the Opossum the Cornu Ammonis extends almost along the whole inner hemispheric wall, and is but slightly folded as compared with that of the Rodentia. That the elevation which I supposed to correspond to the *fascia dentata* and *tænıola cinerea*, might be interpreted as one of the thalamic tubercles, which I considered an open question at the time of my writing the first commmunication, and which I now hold to be disposed of definitely as well as the other supposition.

2nd. There is a molecular accumulation at the base of the cerebral hemisphere, in the common basilar gray, and beneath the elevation of the *corpus striatum*, which may correspond to the lenticular nucleus.

3rd. At and above the level of the emerging third pair of nerves, there is a beautiful nucleus of large multipolar cells, resembling the cells of the auditory nucleus (that is of the large celled division of that nucleus) in contour and in dimensions. This cell group in its situation corresponds to the *nucleus tegmenti* of mammals. I would here note that throughout the animal range, the cells of the *nucleus tegmenti* and the special division of the auditory nucleus referred to seem to keep step in development. This fact would add another link to the chain of evidence attempted by Meynert, who surmised that an auditory tract passed through the cerebellum to the *brachium conjunctivum*, (and therefore through this cell group) on its way to higher projecting fields.

4th. The so-called *nucleus dentatus* of the cerebellum, which should be termed simply *nucleus cerebelli*, since it is not dentated even in all the mammalia, is clearly present in the cerebellum of the Iguana. It can be found at the junction of the cerebellar peduncles with the main cerebellar mass, and consists of well marked cells of moderate dimensions.

5th. The "fasciculus from the habenulæ to the tegmentum" so-called by Meynert, but which Gudden and his pupils correctly state to run from the habenulæ to the *ganglion interpedunculare*, has not been yet identified in animals lower in rank than the mammalia. I find it well-developed occupying exactly the same relations and presenting the same histological peculiarities as with mammals in the Iguana.

6th. The fourth pair does not reach the valve of Vieussens in levels lower than those in which the root has its origin, as in the turtle (*Nanemys guttatus, Chelydra*) and the mammalia, but distinctly arises in the same level in which it reaches the valvule where it decussates. The nerve itself, however, emerges in levels superior to the latter.

7th. While the cells of the oculomotoriotrochlearis nucleus, and those of part of the auditory origin are of large dimensions, those of the abducens, facial, and motor-trigeminal origin are remarkably small. The reduction in size of the cells is as might be inferred accompanied by a reduction in size of their nuclei. This fact suffices to dispose of the recently advanced claims, that motor cells have larger nuclei than sensory ones. The reduction in size of these motor groups and their presenting such a contrast to the great development of the cells in other motor groups in the Iguana, has to my mind much of the enigmatical. The largest cells in the nervous system of the Iguana, are the multipolar cells of the reticular field, (my *ganglion reticulare* in mammals) those of the auditory origin and *nucleus tegmenti* are of the same or nearly the same dimensions.

8th. The mesencephalic nucleus of the fifth pair is represented as in other reptiles by round cells, sunk in the niche between the two optic lobes; they are not spread out on the contour of the central tubular grey, as in mammals, but concentrated more at the median line. Some of the cells can be identified beneath the inter-optic lobes.

9th. The cells of the substantia ferruginea of man are represented by a group of numerous small ganglionic bodies, whose connection with the fifth nerve is clearer than in the mammalia.

10th. The auditory nerve fibres send a powerful strand which decussates with its fellow in the raphe. In its course each strand traverses or circumscribes the posterior longitudinal fasciculus. This same strand is found in the mammalia, but in the latter it is deeply seated; in the Iguana it is more superficial, and the erroneous inference might be drawn that this strand in the reptile is equivalent to the *striae acustici* of mammals. The latter are however, absent in reptiles, and although in some species visible eminences are formed at the floor of the fourth ventricle, crossing at right angles the longitudinal eminences of the posterior longitudinal fasciculi; these are the homologues of the more anterior and concealed part of the auditory decussation of mammals.

11th. In no reptile have the nuclei of the columns of Goll and Burdach been identified. In the Iguana I can readily identify them, although much smaller than the corresponding nuclei of the mammalia. Their demarcation is, however, distinct.

12th. In the Iguana as in the turtle there is an accumulation of numerous multipolar cells at the raphe in the

level of the junction of the cord and oblongata. In addition a group of remarkably attenuated cells is found at the origin of the spinal accessory. These cells are so much elongated and their protoplasm has been so much narrowed that but for the discovery of a nucleus in one or the o her cell, one might consider them a bundle of axis cylinders. These are better developed in turtles than in the Iguana, and better in fresh water species than in the *Thallassochelys mydas*. In no turtle have I found the cells of the raphe very large, but in the Iguana I have discovered a few very large cells in the same level and location as those first described by Dr. J. J. Mason for the Alligator.

13th. In my first paper I indicated the existence in the Iguana of a hitherto undiscovered pair of lobes or tubercles between the optic and post optic lobes. I have also indicated their homology with a concealed pair in the turtle and alligator. At the time I did not describe the topographical relations minutely. Normally—if I may use the expression—as in the turtle and alligator, the newly discovered ganglia lie at the margin of the central tubular gray of the mesencephalon, in the anterior part of the *corpora quadrigemina*. As we go more posteriorly they are found to extend more dorsally, until in the turtle, for example, they nearly touch in the median line just at the posterior fifth of the optic lobes, where they cease. In the Iguana the relations are the same, but instead of terminating before the posterior margin of the optic lobes, they extend further backwards and prominate at the surface of the brain, as two sharply marked buttons. Their structure is the same in all reptiles so far examined, a molecular basis and small roundish cellular elements. In anterior levels nerve fibres can be seen entering them in strands, from the arched fibre mass which is found beneath the deep gray layer of the optic lobes. Although all surmises as to the function of the inter-optic lobes are as yet strictly hypothetical; yet from the fact that they are directly connected with the central tubular gray, and are under the fascicular subjection of the optic lobes, and that they are well developed in reptiles, and poorly, if at all, developed in mammals, one might suspect them to have some relation to the innovation of the Harderian gland, just as the mesencaphalic nucleus of the fifth pair may be looked upon as the probable centre for the innervation of the lachrymal gland proper.

RECENT PROGRESS OF SCIENCE.

Rev. Samuel Fleming, LL.D., Ph. D.

The progress of science within our own times has been wonderful. Prof. Helmholtz uses the following language: "The contemplation of the astounding activity in all branches of science may well make us stand aghast at the audacity of man, and exclaim with the chorus in the Antigone: Who can survey the whole field of knowlege? Who can grasp the clues, and then thread the labyrinth?" Every department of science has been vastly extended, and every votary of science stimulated to untiring efforts to survey this field, not only, but to enter the secret chambers of knowledge to find the treasures concealed from the human mind, until modern discoveries, modern analysis, and modern invention have combined to make those hitherto hidden facts of science known, and available for practical benefits to human society.

The exact science, Mathematics, has found ample room for the application of its principles and methods of determining the content of all material existences and relations. The sublime science, Astronomy, has reveled in its excursions into illimitable space, adding new triumphs, discovering new facts pertaining to the constitution of the stellar universe, and the relations of the celestial masses, measuring, by the agency of light, the immense distances, magnitudes and motions of the tiny objects which the natural eyes behold in the expanse above, and in former times regarded as "fixed stars." The profound science, Geology, has carried us back into the illimitable depths of past duration, to contemplate the usually slow process by which the earth has been changing from its primordeal, nebulous condition, to that in which it has become fitted for living and rational beings, adding new testimonies of the rocks to the truth of Scripture, expressed by the significant language: "Of old hast thou laid the foundations of the earth." The widely related, efficient science, included in the scope of terrestrial Mechanics, has found abundant use for its forces, and the practical application of its dynamics, in the constantly increasing demands of human society. The splendid and delicate science, Chemistry, has exulted in its new and valuable discoveries in the realm of atoms and molecules, verifying the atomic theory, and adding new evidences that many of the supposed elements of matter are really compounds, and must yield to the searching analysis which finds them to be but molecules composed of two or more atoms. The vast and richly diversified science, Biology, has yielded its living evidences of the progressing series of organic natures, and of the vast scope of its history, extending its relations to ancestries, the periods of whose origin belong to the immeasurable epochs of palæontological history, The crowning, all-conserving science, Anthropology, has added new evidences of its superiority in importance, as it stands highest in the scale of associated sciences; and while it has maintained this highest rank by maintaining the honor of its subject-matter, its votaries have found its latest and greatest achievement in the evidences of a formal psychical constitution as the basis of mental action.

It is not the aim of the writer to pursue the history of the development of the sciences, exhaustively, but to indicate some of the lines of progress.

The brilliant discoveries in Astronomy, within the past few years, have added largely to the wealth of this noble science, fascinating the student, and inspiring to new achievements. Previous to the present century, the solar system included seven primary planets as having at that time been discovered. In the year 1800 a new planet was discovered, and designated an asteroid, or small star,—but it is more properly called a planetoid, or small planet. The name by which this is known is Ceres, after the reputed originator, or god, of corn. It was an event of so great interest to astronomers that it was announced with much eclat that "The long-expected planet between Mars and Jupiter had been discovered." Soon after, three more were observed. Since that time, by means of the greatly increased power of telescopes, more than two hundred have been added by discovery, all being very small. Many others will be found. The problem still to be determined has been, whether these planetoids are "fragments of a broken world," as formerly supposed, or separate condensations from cosmic matter, instead of forming one large body, as in the case of other primary planets. It is not probable, however, that a cosmic mass exploded at any one period, producing such fragments in such positions in their orbits as they maintain, nor that such original mass was so dissipated by the action of a propulsive or radiate force at one time, as to resume its original nebulous state. The second hypothesis is the more probable, viz.: of separate condensations from original nebulosity.

Neptune, one of the largest planets, and nearly twice the distance of Herschel from the sun, was discovered in 1846 by M. Challis, of Paris, and its elements and orbit determined by Le Verrier. The discovery of this planet furnished a satisfactory explanation of the aberrations of the planet Herschel, caused by the approximations of Neptune, though distant, at its nearest point, more than a billion and a half miles. This increase of the number of the solar family furnished an additional illustration, on a grand scale, of the laws of universal gravitation and

of celestial mechanics. Added to this have been discoveries abundantly confirming the theory of stellar motion in groups, clusters and nebulæ, "the places of more than 200,000 stars having already been determined," and we have some conception of the vastness of human achievements, and of the possibilities still awaiting discoveries in this illimitable "field of ether."

The universality and laws of primary force, denominated gravitation, have been subjects of exceeding interest, as they pertain to this primary mode of motion. The fact of an attractive Force acting either upon or within bodies by which they tend to approach each other, arrested the attention, about the year 1600, of the elder Galileo, who extended the principle to all terrestrial bodies, Newton, eighty years afterward, studying this principle, and at the suggestion, it is said, of the fall of an apple, found that there was a definite increase of velocity of bodies approaching the earth, and also that the same kind of attractive force must apply to the moon, while a centrifugal force, either generated from the attractive force, or originated from an extraneous force, continued this secondary planet around the earth. This was the first grand step toward the discovery of the laws of gravitation, applicable to the motion of the earth around the sun, and, generally, to all planets. More recently the principle has been applied to comets, stellar and other masses.

Geology, while below chemistry in the order of nature and classification, had made far less progress in development at the commencement of the present century, a fact which might have been presumed, inasmuch as the latter science has ministered especially to the wants of mankind. According to Buckland, it was at that time "without a name." The general features of geology had been sketched by Leibnitz and Hooke more than a century previous. Near the beginning of the present century the outlines of the subject were classified into three general divisions of formations—the primitive, the secondary and the tertiary. These became the subjects of investigation, historically, in the order named. The first, especially, by Werner, of Germany, who examined chiefly the primitive and transition rocks. The second by Wm. Smith (English), whose observations were first published in 1799. The third by Cuvier and Brougniart whose works upon "Organic Remains" and "Mineral Geography" were published in 1808. During the past half century this science has advanced with other sciences, with vastly increased interest and success, rendering this one of the most fascinating, especially in more recent times, in yielding its stores of facts pertaining to the glacial period, the deposition of metallic substances, experiments showing the order and conditions of the cooling processes, resulting in the different mineral states, and the wonderful revelations of paleontological history, together with many other facts of great interest, but which cannot, in this paper, be especially given. These give abundant confirmation to the theory that immense periods of time, measured by millions of years, have passed during this history, dissipating the doctrine formerly held by many as taught in the Scriptures, that the heavens and earth were created, out of nothing, about six thousand years ago.

Among the departments of science which minister to the wants of human society, none has awakened the spirit of invention and improvement at all to compare with that of Mechanics. With the increase of knowledge, there has been a correspondingly increasing demand for instruments of discovery and analysis, not only, but for the application of scientific skill in the invention of motive powers and the means of the transmission of intelligence, as well as implements of handicraft, of agriculture, etc, The steam power, first utilized by the invention of a machine in 1655, and improved by Watt in 1774, inaugurated its grand work for human society in 1806, when Robert Fulton, after repeated experiments, applied this power to the propulsion of vessels, first on the Hudson river, amazing the thousands who witnessed the successful experiment, and introducing a new propelling power to vessels upon the sea, now bearing their burdens, estimated by millions of tons, on every river and over every lake and sea of earth. This power has added incalculable millions to the material wealth and strength of every civilized nation. The last world-wide application of this power, besides its innumerous minor applications to all kinds of mechanical work, was inaugurated in 1821, when it was successfully applied to the propulsion of railroad trains.

In 1819 Electro-magnetism was first applied to mechanical purposes; and in 1831 the Magnetic Telegraph, for the transmission of intelligence, was invented and successfully applied. And now, even the comparatively coarse medium, air, has aided in business and social communications, at trifling expense, by means of the recently invented Telephone and the Phonograph.

Chemistry has shared richly in the results of recent scientific progress, and has ministered richly to the wants of human society. Three centuries ago, Paracelsus boasted of possessing the "philosopher's stone", by which the baser metals were said to be transmuted into gold; but he gave a new direction to the efforts and objects of Alchemy, insisting that its chief aim should be the preparation of medicines of different kinds for different diseases. But Chemistry, as a science, must date its commencement two centuries later, when the analyses of distinguished scholars, as Scheele, of Sweden, and Dr. Black, of Glasgow University, and the Academies of Science at Berlin and Paris, determined important principles of this science.

The discoveries of Sir Humphrey Davy, in the early part of the present century, gave a new impetus to this branch, leading to chemical analyses and the establishment of chemistry as a science. These have been followed by eras of progress which have brought the subject to a high degree of perfection. Now, the four elements of the ancients, and of the alchemists of comparatively recent times—earth, air, fire, and water—have been found by successive analyses to contain sixty-five elements, the last four having been detected by the new and wonderful method called the Spectrum Analysis. It may be here stated what this method is, for the gratification of any whose attention may not have been called especially to it.

It is well known that a spectrum is an image formed by the light of the sun, or any other luminous body, either as direct or reflected rays, passing through a triangular piece of glass called a prism. The colored lines thus formed by differently refracted and dispersed rays, reveal the nature and qualities of the elements contained in the luminous body by the different colors, combinations, and the phenomena presented, compared with previous results of experiment in the laboratory, upon light reflected from different mineral substances. It has been found that every kind of mineral substance, whether in the form of a solid, gas, or nebulous matter, when in a state of intense luminosity, possesses the capacity to emit a specific color, with its accompanying mixed lines. This being known, when a new body is analysed by its light, its constituents are determined by the lines of light. Thus the solar envelopes, protuberances, etc., of the sun are examined by the analysis of the solar spectrum. By this method, the character of comets, meteors, or other celestial masses are determined. By this the problem of the sudden appearance or disappearance of stellar masses is explained, by determining the state of the mass thus emitting light, and the conditions of luminosity. What the telescope has failed to determine in respect to the elements and qualities of bodies, or the nature of nebulous masses, whether such masses are clusters of stars in the infinite distance, or of original, unformed nebulous matter, the spectroscope has accomplished; and what has been held by most astronomers as a theory, has become

confirmed as a fact, that, as Prof. Schellen says, "luminous nebulæ actually exist as isolated bodies in space, and these bodies are masses of gas." Thus, clusters, groups, stars and planets, are in process of genesis from primeval cosmic matter, and Cosmology may be regarded as a science, established by the aid of art in the construction of larger telescopes, and their new associate in the field of stellar research, the spectroscope; these bring within the scope of observation new facts, and confirm the generally received theory of the nebular constitution and the genesis of the stellar and planetary systems from such original cosmic matter.

The conservation of all the lower departments of science to the wants of man, in his individual and social relations, gives a vast superiority of rank to Anthropology. In recent times, the chief points of practical importance in the progress or development of this science have pertained to Sociology. Researches in special lines of investigation have furnished many facts of great interest pertaining to antiquities, archives of ancient cities, inscriptions upon rocks, hieroglyphics and monuments, which have yielded abundant fruits to explorers, and vastly increased the knowledge of particular races and languages; while increasing evidences are furnished that the antiquity of the human race is much greater than that indicated by the generally accepted chronology.

In the department of Philology, great progress has been made during the period of our own times. Comparative Philology is no longer confined to the Latin and Greek of the ancient languages, and two or three of the modern languages, but every language of the globe is yielding rich fruits bearing upon history as well as philology; especially has the Sanscrit, the mother of all the Indo-European languages, received special attention, resulting in the establishment of professorships of the Sanscrit in several colleges.

But questions of the highest interest pertain to Psychology, especially relating to our psychical nature and its connection with our physiological constitution, to the phenomena of "Unconscious cerebration," and other facts which have elicited research in the modes of receiving and retaining sensations and the memory of facts, and into the medium of transmitting such impressions. Such inquiries have led to the adoption of the following theory of accounting for these phenomena, viz.: that the psychical constitution is not simply mental or spiritual, but is *dual* or two-fold, consisting of two substances we may conveniently term respectively *etheral* and *spiritual*. The following rational deductions are given as the only satisfactory hypotheses pertaining to our interior being, viz.: That the great rapidity of the transmission of impressions, being at least 100 feet per second from the extreme parts of our physical system to the brain, or requiring but one-fifteenth of a second to produce a sensation, involves the necessity of the existence of an ethereal substance permeating the nerves, and hence called "nervous ether," which forms the elementary substance of the formal psychical nature. That, as the physical germ is the initial organism of the future physical body, "potentially alive," in the germinal state, so this nervous ether contains the psychical germ or initial organism of the future psychical body, potentially perfected, and which emerges, in its real or developed form, upon the death of the physical body, or properly its separation from the soul, or interior being. That the psychical nature, while connected with the physical, forms the basis of vital action, continuity and identity; and that the mechanism of thought and feeling involves the necessity of two psychical centres of activity, corresponding with the brain and heart, viz.: the psychical *sensorium*, which is the seat of intellectual action, the basis of sensation, memory, etc., and the psychical *cardium*, the seat of the emotional and sympathetic affections.

Scientific progress has both increased the number of special sciences and extended the limits of those previously known. This has created the necessity of the division of scientific research, inducing students to pursue single lines of inquiry, the result being more thorough and extensive knowledge of the respective departments, which have become the common heritage. Examples of this devotion to special sciences are now numerous in every department, as in the case of the late Prof. L. Agassiz, who devoted many years to the study of animalculæ. In the history of plants and animals, species, genera, and even classes have been multiplied, as individuals have devoted their lives to these subjects, with all the helps at command, leaving no depths unexplored. The anatomist and physiologist no longer confine attention to the human structure, but find in comparative anatomy and physiology many types and characteristics brought forward and perfected in the higher orders, or old forms substituted by new, till finally, in the human constitution the completed form best adapted, not to the lower purposes of physical strength and endurance, by which the animal subserves human ends, but the best form for the higher ends of intellectual, moral and social natures by which man is evidently distinguished above the brute.

This division of labor has been found essential in application to the numerous sciences now demanding vastly increased forces of professional teachers in colleges and universities. Now, a college can scarcely claim the name of a liberal institution of learning in which one professor is required to associate sciences so unnaturally connected as Mathematics and Moral Philosophy, or Chemistry, Botany and Pharmacy, as in some European colleges a century ago. A comparison of the courses of study and the professorships in colleges in our country during the past thirty or forty years will exhibit the marked advancement of the sciences, and the increased requirements of the present time. In 1837, Geneva College, now Hobart College, Geneva, N. Y., of which the writer was a student, contained a professorship of "Mathematics and Natural Philosophy;" of the "Latin and Greek languagess;" of "Modern languages, History and Belles-Lettres," to which was added Rhetoric and two other mixed professorships. For the year 1849—1850, the catalogue of Western Reserve College, Hudson, O., of which the writer had been a theological student, exhibits the following: The institution embraced three departments: General Science, Medicine, and Theology, besides a preparatory department. Five professors gave instruction in General Science, or the Literary department; one of which was the professor of the "Latin and Greek;" one of "Chemistry, History, Medical Jurisprudence (in the Medical department), and Natural History,"—the latter embracing several branches, including Geology! and one professor of "Modern Languages." Great advancement upon this order is now exhibited in the principle colleges of our land. I here name only three: In 1875, Lafayette College, Easton, Pa., had twenty professors and adjunct professors, besides tutors, assistants and lecturers—twenty-seven in all. The University of Wooster, O., in 1876, had thirteen instructors in the Literary department, and the same number in the Medical department. The Michigan University, Ann Arbor, Mich., in 1877, had, in all departments, fifty-five instructors.

CAUSE OF THE BLUE COLOR OF CERTAIN WATERS.

By Prof. John Le Conte.

The consideration of certain facts clearly indicates that the real cause of the blue tints of the waters of certain lakes and seas, is to be traced to the presence of finely-divided matter in a state of suspension in the liquid. We have seen that Sir I. Newton, and most of his successors as late as 1869, ascribed the blue color of certain

deep waters to an inherent selective reflecting property of its molecules, by which they reflected the blue rays of light more copiously than the other rays of the solar spectrum. Since the researches of Soret, Tyndall and others, this selective reflection has been transferred to the finely-divided particles which are known to be held in suspension in greater or less abundance, not only in all natural waters, but even in the most carefully distilled water. When the depth of water is sufficiently great to preclude any solar rays reaching the bottom, then the various shades of blue which are perceived under similar conditions of sunshine, will depend upon the attenuation and abundance of materials held in suspension; the purity and delicacy of the tint increasing with the smallness and the degree of diffusion of the suspended particles. Moreover, it is evident that Tyndall is quite correct in assigning to "true molecular absorption" some agency in augmenting "the intense and exceptional blueness" of certain waters; for it is obvious that the "blue of scattering by small particles" must be purified by the abstraction of the less refrangible rays, which always accompany the blue during the transmission of the scattered light to the observer. It seems to be very certain that were water perfectly free from suspended matter and coloring substances in solution, and of uniform density, it would scatter no light at all. "But," as Tyndall remarks, "an amount of impurity so infinitesimal as to be scarcely expressible in numbers, and the individual particles of which are so small as wholly to elude the microscope," may be revealed in an obvious and striking manner when examined by a powerfully concentrated beam of light in a darkened chamber. If the waters of the lakes and seas were chemically pure and optically homogeneous, absolute extinction of the traversing solar rays would be the consequence if they were deep enough. So that to an observer floating on the surface, such waters would appear as "black as ink," and apart from a slight glimmer of ordinary light reflected from the surface, no light, and hence no color would reach the eye from the body of the liquid. According to Tyndall, "in very clear and very deep sea water, this condition is approximately fulfilled, and hence the extraordinary darkness of such water." In some places, when looked down upon, the water "was of almost inky blackness—black qualified by a trace of indigo." But even this trace of indigo he ascribes to the small amount of suspended matter, which is never absent even in the purest natural water, throwing back to the eye a modicum of light before the traversing rays attain a depth necessary for absolute extinction. He adds: "An effect precisely similar occurs under the moraines of the Swiss glaciers. The ice is here exceptionally compact, and owing to the absence of the internal scattering common in bubbled ice the light plunges into the mass, is extinguished, and the perfectly clear ice presents an appearance of pitchy blackness" ("Hours of Exercise in the Alps;" "Voyage to Algeria to Observe the Eclipse," Am. Ed., N. Y., 1871, pp. 463–470). In like manner the waters of certain Welsh tarns, which are reputed to be bottomless, are said to present an inky hue. And it is more than probable that the waters of the Silver spring, whose exceptional transparency has been previously indicated, would, if they were sufficiently deep, present a similar blackness, or absence of all color by diffuse reflection.

It remains for us to explain the cause of the green tints which the waters of certain lakes and seas assume under peculiar circumstances. These green colors manifest themselves under the following conditions, viz: (*a*.) In the finest blue water, when the depth is so small as to allow the transmitted light to be reflected from a bottom which is more or less white. Thus, a white sandy bottom or white rocks beneath the surface of the Lake of Geneva, or the Bay of Naples, or of Lake Tahoe, will, if the depth is not too great or too small, impart a beautiful emerald green to the waters above them. (*b*.) In the finest blue water, when a white object is looked a through the intervening stratum of water. In the blue waters of the sea this is frequently seen in looking at the white bellies of the porpoises, as they gambol about a ship or steamer. In a rough sea, the light which has traversed the crest of a wave and is reflected back to the eye of the observer from the white foam on the remote side, sometimes crowns it with a beautiful green cap. In March, 1869, I observed this phenomenon in the magnificent ultramarine waters of the Carribbean sea. A stout white dinner plate secured to a sounding line, presents various tints of green as it is let down into the blue water. Such experiments were made by Count Xavier de Maistre, in the Bay of Naples, in 1832; by Prof. Tyndall, in the Atlantic ocean, in December, 1870, and by the writer in Lake Tahoe, in August and September, 1873. (*c*.) In waters of all degrees of depth when a greater amount of solid matter is held in suspension than is required to produce the blue color of the purer deep waters of lakes and seas. Thus, Tyndall, in his "Voyage to Algeria to observe the Eclipse," in December, 1870, collected 19 bottles of water from various places in the Atlantic ocean between Gibraltar and Spithead. These specimens were taken from the sea at positions where its waters presented tints varying from deep indigo blue, through bright green to yellow green. After his return to England, he directed the concentrated beam from an electric lamp through the several specimens of water and found that the blue waters indicated the presence of a small amount of suspended matter; the bright green a decidedly greater amount of suspended particles, and the yellow green was exceeding thick with suspended corpuscles. He remarks: "My home observations, I think, clearly establish the association of the green color of sea water with fine suspended matter, and the association of the ultramarine color, and more especially of the black indigo hue of sea water, with the comparative absence of such matter." ("Hours of Exercise in the Alps;" "Voyage to Algeria to observe the Eclipse," Ed. cit. ante, pp. 464 et 467.)

There is one feature which is common to all of the three above indicated conditions, under which the green color manifests itself in the waters of the lakes and seas, viz: When a white or more or less light-colored reflecting surface is seen through a stratum of intervening water of sufficient purity and thickness. Condition (*c*,) is obviously included; for it is evident that a background of suspended particles may, under proper conditions, form such a reflecting surface.

Inasmuch as under these several conditions, more or less of transmitted light is reflected back to the eye of the observer, it is evident that the rays which reach him carry with them the chromatic modifications due to the combined influence of the selective absorption of the water itself, and the selective reflection from the smaller suspended particles. Hence, the chromatic phenomena presented, being produced by the mingling of these rays in various proportions, must manifest complex combinations of tints, under varying circumstances relating to color of bottom, depth of water, and the amount and character of the suspended matter present. In the explanations of the green color of certain waters by the older physicists, we recognize the full appreciation of the influence of selective reflections in the productions of the phenomena; but they seem to have overlooked the important effects of the molecular absorption. We have seen that Sir I. Newton regarded the green tints of sea-water as due to the more copious reflection of the violet, blue and green rays, while those constituting the red end of the spectrum are allowed to penetrate to greater depths. ("Optics, loc. cit. ante.") Sir H. Davy ascribes it, in part, to the presence of iodine and bromine in the waters, imparting a yellow tint, which, mingled with the blue color from pure water, produced the sea-green. ("Salmonia, Collected Works," Vol. 9, p. 201.) In like

manner, Count Xavier De Maistre ascribed the green tints to the yellow light, which, penetrating the water and reaching the white bottom or other light-colored submerged objects, and being reflected and mixed with the blue which reaches the eye from all quarters, produces the green. ("Bibl. Univ.," Vol. 51, pp. 259–278, Nov., 1832; also Am. J. Sci., first series, Vol. 26. pp. 65–75, 1834.*). On the other hand, after Bunsen, in 1847, had established that chemically pure water extinguished the rays of light constituting the red end of the solar spectrum more copiously than those of the blue extremity, so that the transmitted tints were more or less tinged with blue, some chemists were inclined to attribute the green color of certain waters to the presence of foreign coloring substances. Thus Bunsen himself explained the brown colors of many waters, especially of the north-German inland lakes, as produced by an admixture of humus; but he considered the green tints of the Swiss lakes and silicious springs of Iceland as rising from the color of the yellowish bottom. (Vide. loc. cit. ante., p. 44, et seq.) Similarly we find that Wittstein, in 1860, from chemical considerations, concluded that the green color derives its origin from organic admixtures, because the less organic substance a water contains the less does the color differ from blue; and with increase of organic substances the blue gradually passes into green, and ultimately into brown. This is likewise the view taken in 1862, by Beets, for he insists that in all waters the observed color of the liquid is that of the transmitted light, and not, in any case, of the reflected light. Moreover, he maintains that Newton, De Maistre, Arago and others were mistaken in classifying water among those bodies which have a different color by transmitted light to that which they have by reflected light. (Loc. cit, ante.)

We have already shown that if the waters were chemically pure and perfectly free from suspended particles, the red rays of the traversing solar light would be first absorbed and disappear, while the other colored rays pass to greater depths, one after the other being extinguished in their proper order, viz., red, orange, yellow green, blue and violet, until at last there is a complete extinction of the light in the deeper mass of the liquid. But the presence of suspended particles causes a part of the traversing solar light to be reflected, and according as this reflected light has come from various depths, so will the color vary. If, for example, the particles are large, or are abundant and freely reflect from a moderate depth, and prevent reflection from a greater depth, the color will be some shade of green.

When the water is shallow and a more or less light-colored bottom, or a submerged object reflects the transmitted light to the observer through the intervening stratum of liquid, it is evident that the chromatic tints presented must be due to the combined influence of the selective absorption of the water itself, and the selective reflection from the smaller suspended particles.

In other terms, under these conditions, the tints are produced by the mingling of the blue rays with the yellow, orange or red; so that the resulting hues must generally be some shade of green. In short, all the facts established by modern iuvestigations seem to converge and point to the admixture of the blue rays reflected from the smaller suspended particles with the yellow orange and red rays reflected from the grosser matters below, as the true physical cause of the green tints of such waters.

The establishments of the very important function of solid particles held in suspension in water, in producing chromatic modifications both in the scattered light and in the transmitted light, serves to reconcile and to harmonize the apparent discrepancies and contradictions in the views of physicists who have investigated the color of water.

We have already seen that Sir I. Newton and most of his successors, as late as 1847, regarded water as belonging to the opalescent class of liquids, in which the diffuse reflected light and the transmitted light present more or less complementary tints; the former partaking more of the colors constituting the blue end of the solar spectrum, while the latter presented more of the hues belonging to the red extremity. On the contrary, the more recent and more accurate experiments render it quite certain that in distilled water the rays of the red end of the spectrum are more copiously absorbed than those of the blue extremity; so that the emergent transmitted tint is yellowish green or greenish blue. At first view, these results appear to be discordant and irreconcilable; but, it will be recollected, that while even the most carefully distilled water contains a sufficient amount of suspended matter, to scatter enough light, to render the track of the traversing concentrated solar beam visible, yet, in this case, the selective reflection of the blue rays, due to the suspended particles, is not adequate to neutralize the selective molecular absorption of the rays toward the red end of the spectrum. Nevertheless, as has been previously shown, the addition of very minute quantities of diffused suspended matter confers on distilled water the dichroitic properties of an opalescent liquid.

The presence of an extremely small amount of suspended solid corpuscles, by selectively reflecting the shorter waves of light, is sufficient to neutralize and overcome the selectively absorbent action of the molecules of water on the longer waves; and thus, to impart yellow, orange or red tints to the transmitted beam. Moreover, it is very questionable whether any natural waters are sufficiently free from suspended matter to deprive them of these dichroitic characteristics.

Under this aspect of the subject, the views of Newton, derived from the observations of Halley, those of Hassenfratz deduced from his own experiments, as well as the explanations of the green tints of certain waters given by De Maistre, Arago and others, completely harmonize with the conclusions deducible from modern researches, provided the property of selective reflection is transferred from the aqueous molecules to the finely-divided particles held in suspension.

As a striking illustration of the slight causes which sometimes transform the purest water into an opalescent or dichromatic liquid, it may be interesting to detail one of my own experiences. On the 21st of Dec,, 1878, the series of glass tubes employed in my experiments (as previously indicated), being filled with distilled water, the transmitted solar beam presented when received upon a white screen in a darkened room, the usual yellowish-green tint of my winter observations. On the 24th of December, or after an interval of three days, durwhich all parts of the apparatus had remained *in situ*, I was much surprised to find that the transmitted solar beam was enfeebled, and presented an orange red color with no tinge of green. Puzzled to discover what could have produced so marked a change in the optical properties of the liquid, the "scientific use of the imagination" pictured the possible development of ultra-microscopic germ, infusoria, *bacteria*, *confervæ*, etc. The next day (December 25th), the same phenomenon presented itself, when I called the attention of my assistant, Mr. August Harding, who had kindly prepared the arrangement of the tubes, to the anomalous change that had taken place in the color of the transmitted beam. He suggested that as he had used alcohol in cleaning the glass plates, closing the ends of the tubes, and as the plates were secured to corks by means of Canada balsam, the alcohol absorbed by the corks, being gradually diffused, dissolved some of the balsam, which solution, mingling with the water, might produce a fine resinous precipitate, which might stifle the transmitted beam and

* Similarly, Arago has very ingeniously applied the same principles to the explanation of the varying colors of the waters of the ocean under different circumstances, showing that when calm it must be blue by the reflective light, but when ruffled the waves acting the part of prisms, refract to the eye some of the transmitted light from the interior, and it then appears green. ("Comptes Rendus," tome vii., p. 219, July 23d, 1838.)

scatter the rays of shorter wave length, thus leaving the orange-red rays predominant in the emergent light. This view was speedily verified by a critical examination of the track of the traversing beam. A sensible turbidity was visible, in the darkened room, at the extremities of the column of water adjacent to the corks securing the glass plates; and the light diffused latterly at these portions, when examined by Nicol's prism, was found to be distinctly polarized. The emergent beam examined by the spectroscope, exhibited orange and red in full intensity; but the yellow and green were greatly diminished. Ten days later (January 2, 1879) the solar beam traversing the same column of water emerged much brighter than on Christmas day, and the tint was orange tinged with yellow and red. This long repose caused, doubtless, some of the resinous precipitate to become more generally diffused, or to subside, and thus diminished the turpidity of the liquid. The recognition of the dichroism imparted to water by the presence of finely-divided particles in suspension, serves, likewise, to harmonize the conflicting views promulgated by physicists who have studied the chromatic phenomena presented by this liquid. Some claim that the rays of higher refrangibility are more copiously withdrawn by absorption; while others maintain that the rays of longer wave lengths are more absorbed. In many cases the chromatic tints ascribed to selective molecular absorption are unquestionably due to selective diffuse reflection from the ultra-microscopical corpuscles which are held in suspension. (Vide Jamin's "Cours de Physique," 3d ed., tome 3, p. 447, *et seq.*)

ON THE IMPORTANCE OF ENTOMOLOGICAL STUDIES.*

"Occasionally, at the present day, we may hear insects and entomologists spoken of as 'bugs' and 'bug-hunters' —epithets applied in derision to what are regarded as petty objects and trivial pursuits. Such views only betray an ignorance which is equally pi iable and inexcusable. The study of insects has assumed an importance in its direct application to agriculture, horticulture and sylviculture, second to no other department of natural history. It has called to its aid some of the best intellect of the country. Its literature has become extensive and assumed a high rank. Our State governments, in response to demands made upon them, are appointing State Entomologists. Our General Government is making liberal appropriations for entomological work in the Department of Agriculture at Washington, and also for sustaining a special United States Entomological Commission, now in the third year of its operations, charged with the investigation of a few of our more injurious insects.

"The study of insects assumes an importance in this country far greater than in any other part of the world. No where else does mother earth yield in such variety and in such abundance her agricultural products; after supplying to repletion our own people, the excess is distributed to every quarter of the globe. Few, surprisingly few, of these varied products are native to our soil. Nearly all of our fruits, grasses, cereals and vegetables, and perhaps three-fourths of our weeds are of foreign importation—mainly from Europe. With their introduction, very many of the insects that preyed upon them were also introduced, or have been subsequently brought hither. But unfortunately for us, the parasites which preyed upon them and kept them under control, have for the most part, been left behind. As the result, the imported pests, in their new home, find their favorite food-plants spread out in luxuriant growth over broad acres, where they may ply their destructive work without hindrance or molestation, until some native parasites acquire the habit of preying upon them.

"The grand scale upon which our crops are grown as no where else in the world—demanding for their gathering the invention of special mechanical contrivances, and that horse power should be replaced by steam—has also as its attendant inevitable evil, an enormous increase of insect depredations. This may be illustrated by a reference to our apple-tree insects. * * * * * * "In like manner, any and every crop cultivated on a large scale offers strong invitation to insect attack, and wonderfully stimulates insect multiplication."

PROFESSOR J. A. LINTNER.

CLOUD COLORS.

This P. M., from about 3.30 to sunset, I was witness to a remarkably vivid display of cloud-colors; and thinking that a full description of the phenomena may perhaps help to the understanding of the conditions of the higher atmosphere, I have written out what I saw. The day had been the warmest of the season. The night before was cloudy, and the temperature hardly fell below the freezing point. Light clouds prevailed through the day; at 3.30 the standard and maximum thermometers stood together at 62°, while the maximum sun thermometer registered 119°. The day had been quite still, the direction of the very light wind being from the S. E. The clouds in the neighborhood of the sun were of two varieties, the lower a fleecy and tufted cloud of the cumulus order, moving pretty rapidly from a little north of west, and frequently exhibiting a rapid spiral movement in the filaments, the other would be called cirro-stratus, though not precisely the typical cloud of that name, as portions were quite free from any appearance of structure. In the less dense portions an arrangement in parallel fibres was, however, quite apparent,—one set nearly horizontal, the other inclined at about 45°, the south end upward. The horizontal arrangement predominated, while the other was visible here and there in a detached streamer and occasionally in striæ upon the longer belts, which, hence, were not, as is usual with this cloud, striated perpendicularly to the direction of the bands. These cirro-stratus clouds, which also moved from the west, though with a much less velocity than the lower ones, were the only clouds which showed the rainbow colors. These were exceedingly intense, and changing every moment with such rapidity as to make it very difficult to decide upon the order of the colors, the more so as every filament had its own rainbow, and all were shifting. The red was, however, generally nearest the sun, though sometimes bordered inwardly with intense yellow. The most perfect succession of colors which I caught was in a cloud extending horizontally northward from the sun, in which for a brief interval all the seven colors could be traced following one another, not in the direction of the sun, but vertically, the red uppermost. The violet was, however, so very brilliant as to suggest the beginning of a new rainbow at its bottom, and in a moment this cloud had adopted the form which was most common throughout,—bands of red above and below, with a broader band between of yellow or green or blue. This blue tint was often exceedingly brilliant, tipping both ends of filaments, which were of dull hue in the centre, and bordered above and below with parallel stripes of red. A purple shade was occasionally distinct, surrounded by other colors. This undescribably beautiful display continued over the whole S. W. quarter of the sky, until the sun had been out of sight behind the mountains for more than half an hour.

Though the clouds upon which the colors were observed were of the order in which halos are formed, yet the appearance had very little in common with the halo,—of which we have had a good example within a week. The colors were not only not concentric, but were exhibited successively by different clouds in every direction from the sun, and *at all distances*, from 30°, or, perhaps, 40°, to

not more than 3° or 4°. In fact, about four o'clock the transmitted light was of a splendid green color, tinting the white walls of my room as though through the stained glass of a church. About the time I first noted the colors a strong north wind sprung up, continuing in gusts through the afternoon. F. H. LOND.

COLORADO SPRINGS, *January* 29, 1881.

NOTE ON DR. HENRY DRAPER'S PHOTOGRAPH OF THE NEBULA IN ORION.*

By MR. RANYARD.

*Read before the Royal Astronomical Society, Jan. 14, 1881.

Dr. Draper has sent me an enlarged copy of a photograph of the nebula in Orion, which he succeeded in taking on the night of the 30th of September last. Dr. Draper remarks that September is not the best time of the year, so that he hopes to obtain still better results next summer. The photograph was taken with an exposure of 51 minutes. He does not mention the instrument with which it was taken, but I conclude that it was with his great 27-inch reflector. On the photograph are nine white spots of various sizes; these represent 13 stars in and about the nebula, for the four stars of the trapezium are merged together by reason of over-exposure. In the corner is another small photograph taken with a shorter exposure, and showing three of the four stars of the trapezium. This is not the first occasion on which the stars of the trapezium have been photographed. I, and no doubt many others, have succeeded in obtaining photographs of them. But it is, I believe, the first photograph in which any trace of the nebula is shown. And Dr. Draper may, I think, be very much congratulated on the great success he has attained. The photograph shows the whole of the brighter nucleus of the nebula—sometimes referred to as the "Fish's head." I have compared it with the different drawings of the nebula by Bond, Herschel, Liaponnov, Lassell, Secchi, the Earl of Rosse, and Tempel, and find that it does not correspond exactly with any of them. The drawings differ very greatly amongst themselves, and they differ in type as well as in minor details. They do not appear to differ continuously in order of time, so that the drawings do not afford any proof that the form of the nebula is changing. Photographs will of course afford much more valuable evidence with respect to any such change in the future. The photograph does not show any stars of less than the 9½ magnitude, showing that the brighter masses of the nebula registered themselves on the plate when stars of the 10th magnitude left no trace. If in the future some much more sensitive method of photographing is devised, it will be necessary to contrive some plan by which the brighter parts of the nebula and the light of the brighter stars may be cut off from the sensitive plate during the greater part of the exposure, so as to prevent the irradiation from the brighter parts encroaching over the area occupied by the fainter parts. At present, however, we are very far from being able to photograph, with the sensitive silver compounds* made use of, all that can be seen with the human eye. But even if photography does not make any further advances, photographs such as these will be of very great value in showing the relative brightness of the brighter parts of the nebula.

Mr. Common: I do not agree with Mr. Ranyard, that we must look to photography to explain or prove any change in the form of the nebulæ, because various kinds of plates give different results, and you would not have the same effects produced by the same colored light. I should rely much more on accurate drawings than upon any photographs. If we compare these drawings, here you have [pointing to Father Secchi's drawing] a dark mass with a slope of light running from the left-hand corner down to the right hand. In the other [Lord Rosse's drawing] there is no division, except a large space divided into channels. The latter is wrong and the former clearly right. Before you give details you ought to represent the chief features of the nebula, because it is the features that most readily indicate change. With regard to Mr. Ranyard's remark that no star smaller than the 10th magnitude is shown, there are, I think, two—these fainter stars under the trapezium, which are certainly less than the 10th magnitude.

Mr. Ranyard: I have here the magnitudes given by Liaponnov, and he gives one as the 9th magnitude and the other as the 9th to the 10th magnitude.

Mr. Common: Before we can discuss this photograph we want to know the instrument it is taken with, the focal length, in order to know the size of the image, and the kind of plates used, and the mode of development. If you want to detect any change in the form of the nebulæ you must entirely rely on the hand drawings.

Mr. Ranyard: I think that some considerable scientific use may be made of these photographs; they will at least enable us to compare the relative brightness of the different masses of the nebula as shown on any one photograph, for as far as we know, there is no great difference in the spectrum of different parts of the nebula, and so we have no reason to suppose that the photographic effects of different parts of the nebula in any one photograph would not be proportional to the light.

Mr. Stone: With regard to discrepancies in drawings, I never knew two persons asked to make a drawing of the same faint object make them exactly alike. It is evident that observers draw that which happens to arrest their attention, and one feature will strike one observer, while the attention of another is attracted by something else. A very good instance of this occurred during the eclipse of 1874. Two observers were sitting side by side drawing the corona. The one drew a small nearly quadrilateral corona, while the other drew a large corona with great rays in the equatorial regions. Before a totality was over the observer who had drawn the small corona looked at his neighbor's drawing, and, on looking up again at the corona, recognized the outline which his neighbor had drawn, and commenced to put it on paper when the eclipse ended. There is therefore a great element of uncertainty about drawings, one observer overlooks one part, or is struck by one part, and another by something else.

Mr. Rand Capron: I think that Mr. Commom is right, that photographs of objects taken with different instruments and plates will probably never usefully bear comparison; but I agree with Mr. Ranyard that photographs of the same object taken from time to time with the same instrument and the same plates can most usefully be compared.

Mr. Burton said: I should like to suggest that the difficulty which Mr. Ranyard has referred to, with regard to the irradiation from stars interfering with the fainter parts of the nebula, might be got over by placing a prism of small angle, made of quartz or Iceland spar, between the object-glass and the photographic plate. The images of the stars would be drawn out into lines, while there would be three or four images of the nebula which would not interfere. The principal plane of the prism might then be turned round into a different position-angle, and another photograph taken, so that the spectra of the stars would fall in another direction.

Mr. De La Rue said: I recollect very well the time when the Earl of Rosse's drawing was made. I compared

*[Note by Mr. Ranyard.] It seems probable that the small pencil of light, which passes through the pupil of the eye from the faintest object perceived, produces an actual change in the matter of the rods and cones, which is rapidly obliterated by the circulation and vital processes going on about the retina. This is now, I believe, pretty generally agreed to by physiologists. If in the future the matter acted upon in the rods and cones can be isolated, and the change produced by light can be rendered permanent, it seems probable that, by means of large lenses and reflectors, we may some day obtain photographs of objects too faint to be visible with the naked eye.

it with the nebula with very great interest at the time, and I cannot agree with Mr. Common in preferring Father Secchi's drawing. It seems to me that the Earl of Rosse's drawing is much the more accurate in respect of details. As regards contour and outline, that depends very much upon the amount of light, which impresses one man's eye rather than another's so that the general outline may be extended much more in one case than in another. Lord Rosse's drawing does not give the whole sweep of the nebula, and does not take in so extensive a field as Father Secchi's drawing. Lord Rosse's drawing is better seen in the black upon white print than in the white upon the black ground.

Mr. Common said that there was a great black channel in the nebula, which is well shown in Father Secchi's drawing, but is lost in the Earl of Rosse's drawing. The latter drawing seemed to him too full of detail.*

Mr. Ranyard said although the actual brightness of various parts of an object like a nebula or corona cannot be judged of from the opacity of corresponding parts of photographs, yet a photograph will enable one to tell with great certainty which is the brightest region of the object photographed, and it affords a very valuable permanent photometric scale, by which various degrees of brightness of one region relatively to another may be judged of. For example, Dr. Draper's photograph shows that a nebulous mass on the preceding side of the trapezium is the brightest region of the nebula. This does not correspond with any of the drawings. It is of course possible that the actinic light of the nebula does not correspond with its luminosity as observed by the eye, but this supposition is not very probable, as the spectroscope does not show any striking differences in the composition of the light of the nebula. The photograph enables us to judge very well of the relative magnitudes of the stars involved in the nebula. I have compared the magnitudes of the images of the stars in the photograph as enlarged by irradiation, with the magnitudes of the same stars as given by Liaponnov, and I find that they correspond very accurately. No doubt it may also be assumed that the brightness of various regions of the nebula may be compared with equal safety by noting the opacity of corresponding parts of the photographic film. With regard to Father Secchi's drawing and the drawing of the Earl of Rosse, I agree with Mr. De La Rue that I rather prefer the Earl of Rosse's. It shows a much smaller region of the nebula, and I must remark that I have not much faith in the existence of these outlying nebulous structures shown in Secchi's and Tempel's drawings. If such structures exist the nebula would occupy an area of more than a degree, and it ought to be seen with the naked eye better than with any telescope. Every one is familiar with the way in which a faint structure like the tail of a comet—which can be easily seen with the naked eye—is lost when viewed with the best of telescopes. A telescope of whatever aperture will not increase the brightness of an object occupying a sensible area.

Mr. De La Rue: Lord Rosse's drawing does not embrace such a large area as Secchi's, and you do not see the contour definitely marked as you do in Secchi's. If you cover those parts of Secchi's drawing down to the extent of Lord Rosse's drawing then the difference of outline that strikes Mr. Common would to a great extent disappear.

Mr. Mitchell: If you get a definite chemical compound with which you make your photographic plate, and can obtain a definite exposure, and know the other conditions of temperature, and so on, I think that it can not be doubted that you would have a more reliable record than if the varying conditions of the brain, at one time and another, have to be taken into account. If the condition of one man's brain has to be compared with the condition of the brain of another man, physiological difficulties come in which may be avoided by means of photography. In comparing photographs you have only mechanical differences and physical conditions to consider, which certainly involve much less complication than physiological differences.

* [Note by Mr. Common.] Reference to the drawings here mentioned was only made incidentally, and with regard to one point. As to which of the two is the better one, I have no doubt in my mind, nor need any one have who looks at them with a recollection of the real object. What I wanted to point out was, that owing to a proper contrast not having been made in Lord Rosse's drawing, the general appearance, or what we would tails the leading features, was lost, and a drawing excellent in all the decall fails in these leading features.

ASTRONOMY.

MAGNITUDE OF JUPITER'S THIRD SATELLITE.

On the evening of February 2, Jupiter was passing near the star B. A. C. 303 (73 Piscium, and the opportunity was taken at the Observatory of Harvard College to compare photometrically the third satellite of the planet, with the star. Three observers took part in the work, and four sets of measurements, each consisting of eight single comparisons, were made. The result obtained was that the star was fainter than the satellite by 0.38 magnitudes of Pogson's logarithmic scale. For the magnitude of the star we have 6.16 by the mean of the available estimates on record, and 6.17 by the observations made at this observatory with the meridian photometer. The resulting magnitude of the satellite is 5.28 or 5.29, in close agreement with the value, 5.24, found by a very different method, in the Annals of the Observatory, Vol. XI., p. 276.

SWIFT'S COMET.—We are indebted to Prof. Pickering for the following list of dates on which observations of Swift's Comet (1880 e), were obtained at Harvard College Observatory, by Mr. Wendell:

1880, Nov. 3,	1880, Nov. 27,	1880, Dec. 28,

URANIA.—The first number of the new *International Journal of Astronomy* contains in a very convenient form of 24 demy 4to pages, a number of interesting articles. Among others are the following papers: "Observations of the Spectrum of Comet 1880 d, (Hartwig) at Dunecht," by Copeland and Lohse. "A New Planetary Nebula," by Dr. Copeland. "Observations of Comets 1880 b, c, and d, at Dunecht. "Uber die Auflösung der Lambert'schen Gleichung für Parabolische Bahnen, by Professor Klinkerfues.

PROF. WILLIAM A. ROGERS, of Cambridge, has recently made a visit to Washington to compare the copies of the English and French standards of length, with the standards of our Government deposited at the Coast Survey Office. Prof. Rogers obtained very accurate copies of the yard and metre during January and February, 1880 having made a trip to Paris and London for that purpose.

WE learn of the recent death of Baron Dembowski, the well-known double-star observer, at the age of 69. For upward of twenty-five years he had devoted himself to the re-measurement of the stars of the Dorpat Catalogue, and for this work was awarded in 1878 the gold medal of the Royal Astronomical Society.

BOOKS RECEIVED.

ASTRONOMY FOR STUDENTS AND GENERAL READERS. By SIMON NEWCOMB, L. L. D., and EDWARD S. HOLDEN, M. A. Second Edition, Revised. Henry Holt and Company. New York, 1880. $2.50.

It may be supposed that the joint efforts of Dr. Simon Newcomb and Professor Edward S. Holden to write a work on Astronomy has resulted in the production of a work which may be accepted by the public as a reliable and able exposition of the subject.

The attempt, however, to compose a text book in Astronomy which should be equally applicable to the class of a college, and to the general reader, was a task which presented few elements of success; we are not therefore surprised to find that the authors candidly state in their preface that in spite of the title selected for the book that the work was principally designed for the use of those who desire to pursue the study of Astronomy as a branch of liberal education.

Regarded in this light the work is a great success, for the general reader will find by a careful perusal of this manual that he has mastered all the leading points in the study of Astronomy in sufficient detail, to enable him in the future to fully comprehend whatever he may read on this subject. The work in question may well serve as a model for those desirous of writing scientific manuals; in simple, but forcible language, the most complicated explanations are presented in a form that may be comprehended by a reader of ordinary intelligence without mental effort, while the interest of the student is maintained throughout.

The description of astronomical instruments and their uses forms a valuable portion of the work, and all the details of observatory work are explained by the aid of good illustrations; thus all the methods by which astronomical research is carried on at the present day are described by one who was himself at that time a member of the corps having in charge one of the most completely equipped observatories that has yet been organized.

The three branches, into which Astronomy is now divided, are all ably treated by the authors, and it is not difficult to detect the plan adopted by the authors in dividing their work.

We regret this manual was not considered worthy of a good index, for on this account the book is valueless as a work of reference. In future editions it would be well to remedy this unnecessary defect.

CIRCULARS OF INFORMATION OF THE BUREAU OF EDUCATION. NO. 4, 1880. Rural School Architecture, with illustrations.

NO. 5. English Rural Schools. Washington, Government Printing Office, 1880.

The first paper (No. 4) presents a concise yet complete treatise on the proper construction, heating and ventilation of school buildings, prepared by Mr. S. M. Clark, a well-known architect of Boston. The aim of the paper is not so much to lay down rules to be inconsiderately followed, as to give principles and directions suggestive of the plans best to be followed under a variety of circumstances.

This is a thoroughly practical paper, and the whole subject has been well handled by Mr. Clark, and the pamphlet cannot fail to be most useful to School Boards and Committees. The Commissioner of the Bureau of Education deserves the thanks of all heads of families for ordering the production of this timely publication, which, however, merely applies to rural districts, and we trust the manual treating on buildings for high schools, academies and colleges will be published without delay, as it is a matter of common notoriety that the health of children in many of the large cities, is sacrificed in consequence of the school-rooms being constructed without regard to hygienic principles.

No. 5—Is a description of the condition of rural schools and the progress of elementary education in the rural districts of England, written by Mr. Henry W. Hulbert, late of Middleberry College, based on his personal information. He does not attempt to enforce lessons from his facts, but leaves these to the reflection of the reader.

The facts presented by Mr. Hulbert are most interesting, and would appear to indicate that the effort to educate the masses of the people is making slow but steady progress against the opposition raised against it by certain classes.

We have the authority of Mr. Heller, of the *National Union*, that there was a great cry at first, but advanced education would increase the crime of the land. Of course the contrary has been the real result, and it is stated that there is manifestly less coarseness of manners among the lower classes.

It is admitted, however, that a certain restlessness has been created by advanced education, and "that it has driven children into towns to seek what they consider higher situations, and in some cases it has led to emigration."

LETTERS TO THE EDITOR.

DR. FLEMING'S CLASSIFICATION OF SCIENCE.

To the Editor of SCIENCE:

There are numberless ways in which knowledge may be classified, as the numerous systems of classification put forward show, and it appears to be a very common notion that all knowledge may be put in a serial order showing the elements in logical dependence. However this may be in metaphysical matters, it is certainly not possible to do so in physical philosophy, for the various manifestations of energy are mutually co-related, and starting with any one of them it is possible to develop almost any of the other forms. In the scheme of Dr. Fleming this does not appear, but in the plan of it he places the doctrine of the correlation of forces high up in Physico Dynamic Science instead of making it almost the first division of Physics. The latter as now understood is the science of energy, and energy always involves two factors, one a mass and the other a velocity. When motions are considered in their geometrical relations, apart from mass, the science is known as Kinnematics and as a branch of pure mathematics, it has nothing more to do with physics proper than has geometry, though all problems in physics are more or less mathematical problems, but they become *Dynamic* when mass is involved. Inasmuch as masses of all dimensions, from an atom to the sun, follow the same laws, it surely is not a scientific proceeding to make a grand division here of Astronomy as distinct from the more general division of Mechanics. Astronomy so far as pertains to the genesis of the Stellar Universe is only a development or application of mechanics to large masses of matter. Again the author is mistaken when he says, "Then Natural Philosophy monopolizes the whole field. Now Chemical Philosophy has taken the rank of a distinct department." The fact is that since the discovery that chemism is dependent upon *mass*, the science has been swallowed up entirely in physics, and every so-called chemical problem is a pure physical problem. Chemism is one of the correlated forms of energy and the logical importance is the same as that of heat and electricity.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, FEBRUARY 26, 1881.

INDEX FOR SCIENCE.

In accordance with the promise made in our first number, we have prepared an elaborate Index for Volume One.

Genera and species are printed in italics; also the names of recently discovered stars. There is a separate Subject and Authors' Index, the whole having 4576 distinct references. "SCIENCE" thus becomes a valuable standard work of reference, which should be found in every library. The Index has been sent to regular subscribers; others can obtain it on payment of twenty cents.

THE NEW YORK AQUARIUM.

With the closing of the New York Aquarium the city will lose an institution that might have been made a source of instruction to the people, combined with an agreeable place of recreation, and the causes of its failure to be remunerative may be studied with advantage by those who desire to have a permanent public aquarium in this city, thriving on a paying basis.

We observe that the present proprietor, Mr. Charles Reiche, makes the assertion "that such a place is not appreciated by the people." We consider that such a statement has been amply refuted by the very fair amount of patronage received, even at a price for admission which was practically prohibitory to the majority of those who would have visited the place in thousands.

Neither do we believe that the faults of the management can be charged with the failure, and we have as little faith in the other reasons which have been suggested. In our opinion the whole enterprise was killed by being loaded down with heavy expenses, and too profuse expenditure by those who controlled the finances.

Unfortunately, there was too much money at command from the start, and by the time experience of the proper course to pursue had been gained, the capita had been squandered, and the demoralization which finally led to the ruin, had set in.

To saddle the enterprise with a rental of $10,000 a year for the bare ground on which the building stood was to court ruin, but all the outlays were made on the same extravagant basis. Then came the fatal mistake of appealing for support to the few affluent, and making each admission fifty cents, instead of trusting to the multitude who could and would have paid twenty-five cents.

Even under these circumstances we are now told by Mr. Reiche that *for a time it did pay*. We think this very convincing proof that under more economical management and with a less pretentious establishment, success would have been secured.

On behalf of many scientific men, we extend our thanks to Mr. Reiche for the liberal facilities he has throughout extended to those who desired to visit and make use of the aquarium for scientific purposes; to such the place has always been open and a cordial welcome given. Under instructions, the officers in charge have been courteous in offering the fullest facilities for study and freely gave such specimens as could be spared. How little such opportunities have been appreciated and used by naturalists within reach of the institution reflects little credit on those who should have seized the occasion with avidity.

Unfortunately the facilities were too great, and too conveniently at hand to be appreciated, and because they were offered as a gift they were neglected. The New York Aquarium had the benefit of the services of the best professional collectors in this country, and the coast from Maine to Florida was constantly searched for living species of rare and interesting forms of animal life, and yet many naturalists preferred to waste their time and money, travelling hundreds of miles, to obtain objects which could be had at their very doors.

The same results have happened in Europe under similar circumstances. When Mr. Lloyd, of London, was asked if he thought the aquarium at the Channel Islands would answer, he replied, that he feared it was too near home, too convenient of access; for said he, "I have known persons prefer to travel from to the Bay of Naples to collect specimens, which I had in my aquarium at the Crystal Palace."

We trust that steps may be taken to preserve the fittings of the New York Aquarium, and that they may be replaced in some part of the city where a site will be inexpensive, and that a plan may be arranged for maintaining it on a remunerative basis, which in our opinion should not be a difficult matter; but to secure success we should advise the institution to be placed in the charge of some well-known professional naturalist, who could be well named by Professor Spencer F. Baird.

SMITHSONIAN INSTITUTION.

In its annual report for 1880 the Smithsonian Institution purposes publishing a bibliography of American Anthropology for that year. The list will include not only the titles of works in that special branch, where-ever issued, but also the publications of American scholars in all departments of this science, and you will confer a favor on the establishment by sending it a copy of each of your works upon the subject published during the year 1880. Should this be impracticable, however, please send a list of your own memoirs and of those of the scientific associations with which you are connected, bearing upon Anthropology, in each case giving the full title, author's name, edition, imprint, size, number of pages, maps, engravings, etc. If the publication forms a part of a periodical or of the proceedings of a scientific association, the fact should be distinctly stated. In the case of separate works, references to periodicals in which reviews have appeared should also be given.

In order to give permanent value to this list and to obviate delay in the appearance of the volume, you will oblige the Institution by complying with its request as soon as possible.

SPENCER F. BAIRD,

Secretary Smithsonian Institution.

WASHINGTON, D. C., February 1, 1881.

SCIENTIFIC SOCIETIES OF WASHINGTON.

THE BIOLOGICAL SOCIETY.—At the Biological Society, Friday evening, February 11, the entire evening was spent in discussing the annual address of President Theodore Gill, delivered at the previous meeting. Dr. White and Professor Ward, in company with the President, reviewed the arguments which have been offered by various naturalists, including Professor Burt G. Wilder and Dr. Coues, for the existence of antero-posterior symmetry in the vertebrates. The conclusion reached was, that, while there are many and very plausible reasons in favor of this view, on the whole, the weight of testimony is on the opposite side. Dr. King gave a description of one or two cases of hermaphroditism which had come under his notice. This was the occasion of an interesting discussion as to the meaning of the term and the possibilities of the phenomenon in the human subject. Professor Ward brought forward the arguments of Haeckel for the establishment of a kingdom of nature intermediate between the Vegetable and the Animal Kingdoms.

THE ANTHROPOLOGICAL SOCIETY,—The Anthropological Society met on Tuesday evening, February 15, Vice-President Mason in the chair. The following papers were announced: "Some peculiarities in the use of moods in the principal Neo. Latin Languages."—By H. L. Thomas. "Aboriginal burial cave in the Valley of the South Shenandoah."—By Elmer R. Reynolds. "Amphibious aborigines of Alaska."—By Ivan Petroff. Mr. Thomas, the translator of the State Department, announced that the object of his paper was to follow the history of the Latin rules respecting the sequence of moods in complex sentences in the languages of Southern Europe, commonly called Romance or Neo-Latin. The author directed attention to the fact that numerous editors of the last few centuries had made changes in the moods of Latin verbs in order to bring them under certain fixed rules from which the Latins had never varied. By numerous citations from very old editions these changes were exposed.

The next point elaborated was the national peculiarties which had manifested themselves in the adoption of Latin rules. The Portuguese, Spanish, French, Italian and Romance proper, had all affected the Latin usages in the use of the subordinate subjunctive, but had done this, so to speak, in their own way: which gives to the subject a special ethnologic value.

The author justly paid a high tribute to the opinion set forth by Professor Fay, in a communication made to the Society last year, that we are not to look in classical Latin but in the old Roman folk-speech for the ancestor of these borrowed forms. During the discussion which followed by Professor Antisell, Dr. Welling and the chair, the interesting question was mooted whether in the advance of scientific certitude the use of subjunctive or doubtful forms were not sloughed off.

Dr. Reynolds gave a brief but highly interesting description of a visit to a cave in Page valley, Virginia, near the celebrated Luray cavern, containing numerous human remains. The Smithsonian Institution had sent out many hundreds of circulars, to every post-office in the United States, but had failed to receive information of a single mound or permanent remain in the valley of Virginia. Dr. Reynolds, in the short space of a month traced twenty-five mounds, ossuaries, forts, ateliers, and bone caves. The paper was illustrated with a large collection of human bones, stone implements, and pottery.

AMERICAN CHEMICAL SOCIETY.

THE February *Conversazione* of the American Chemical Society took place Monday evening, the 21st inst. No papers were read, but a number of interesting specimens were exhibited. Among these was a quantity of that poisonous alkaloid, nicotine, which Mr. William Rupp, one of the curators of the society, had himself prepared. Mr. P. Casamajor, by means of a microscope with an 8-10 objective, showed a simple way to distinguish between pure sugar and that adulterated with glucose. The former crystalizes in large and characteristic forms while the glucuse appears much finer, and as poorly defined cystals. So that when the two are mixed no difficulty would be had in distinguishing the adulterated from the pure, provided a microscope was used.

A large piece of glass painted with Balmain's Luminous Paint was exhibited by Mr. M. Benjamin. This paint was discovered in 1877 by Mr. Balmain, an English chemist, and has recently been brought to this country. It possesses the peculiar power of phosphorescence, or the property of absorbing light during the daytime, and then emitting it in the darkness. It is prepared by calcining oyster shells with sulphur, and treating the resulting calcium sulphide with the proper articles necessary to form a paint.

Its uses are numerous; miners lamps are painted with it, and used instead of the ordinary safety lamp; it has been suggested that screens coated with this paint be used for illuminating purposes along the galleries of mines. Its marine applications are very important. the painting of life buoys, and also stationary buoys, so that they can be seen at night-time, the hulls and rigging of ships treated in this manner might prevent collisions. Divers costumes painted with it are found to yield light after the diver has descended, in fact, sufficiently so to enable him to distinguish quite minute objects.

Tunnels may be illuminated by this paint. It has been successfully employed to light railway cars at night time. The time of night is readily told from clocks and watches whose faces are coated with this substance. Signs and advertisements are among the many uses to which it may be put. More appplications will suggest themselves to every one. M. B.

N. Y., Feb. 22, 1681.

ORGANIC HEALING POWERS.

A LECTURE BY RUDOLF VIRCHOW.

[*Translated from the German by the Marchioness Clara Lanza.*]

Andrew Jackson Davis, who is called the "Great Prophet" by his German adherents, thus begins a chapter in his "Harmony"[1] entitled "The Philosophy of Disease:"

"The improvements and progress which have been made in pathological science, are not by any means in keeping with its actual value and antiquity." And then he adds the following:

"The age of a science or doctrine has but little to do with its reliability, importance or progress. Indeed, the great maturity of any doctrine is almost a positive proof that it originated in ignorance, superstition and error."

The "Great Prophet," who conceives all his ideas without the aid of study, and who, moreover, by a peculiar direction of his will, turns from the confining influences of the material world in order that he may enter the "highest state," has entirely overlooked the fact that the ancient science which he disdains, proceeded from precisely similar revelations as those which he produces with so much pride.

Welcker, in his magnificent work upon the "Art of Healing Among the Ancient Greeks,"[2] has given very impressive descriptions of the Epiphania which occurred more than 2000 years ago in the Temple of Æsculapius, and they now possess a double interest in regard to American Spiritualism or spiritualism of any kind, (if we consider for a moment how philologists a quarter of a century ago investigated the question) as to whether the so-called incubation of the Æsculapians was identical with modern clairvoyance. Those seeking to be cured from disease obtained revelations while sleeping or dreaming in the sanctuary of God. Hence medical literature arose, for the afflicted wrote a description of their cures upon the pillars of the Temple or else upon certain consecrated tablets, and from them the forefather of medicine, Hippocrates, collected in the Temple of Kos those memorable "Predictions" which can be considered one of the principle sources of our scientific knowledge.[3]

Did all this spring from "ignorance, superstition and error?" The point perhaps cannot be contested, but it contains, nevertheless, a large portion of veritable experience, and Hippocrates, not withstanding his direct descent from heathens was a too critical and (remarkable as it may seem) a too worldly person not to expose everything which partook merely of a sacerdotal or superstitious character.

In his writings and in those of his followers, there is nothing supernatural to be found. The gods no longer heal the sick. Nature does it, and nature, moreover, does not act in accordance with instantaneous inspiration. On the contrary it is subject to "divine necessity," or rather we should say to eternal and also divine laws.

Since the remote period before referred to, opposition has been openly declared between science and superstitious therapeutics. The latter even now has certainly not died out. The countrymen of the "Great Prophet," that is to say, the medicine men among the North American Indians still boast of their immediate intercourse with the Great Spirit, and perhaps it is the proximity of these people which promotes the increase of spiritualism throughout the United States. One of the nations of North Asia[4] beats a magic drum, while a certain people in South Africa blow an enchanted trumpet in order that the evil spirits of disease may be dispelled. However, we do not need to go so far for examples of this kind. In our immediate neighborhood the traditions of heathenism rise up secretly and flourish, while superstition concerning mystical healing powers is capable of continually bringing forth fresh fruit.

Conjuring, however, during the past century has rapidly declined. I, myself, remember that during my childhood many people of the middle classes where I lived believed in fire conjuring. Even at the present day you will scarcely find one German city where the worth of a fire brigade is not undervalued on account of the possible termination of a conflagration may have in consequence of conjurations.

In one of those old Greek writings, which, on account of its age, has been attributed to Hippocrates, and has for its subject Epilepsy, or the divine disease[5], which, at that time was treated by magic, the author says that those who conferred divine names upon diseases were merely magicians, purifiers, pious beggars, and coxcombs, who gave themselves the airs of God-fearing individuals, but who, in reality, knew no better how to conceal their perplexity than by taking refuge behind the deities.

How many years have passed since then! The Olympian Gods have been shattered for ages; even Christianity has by degrees become an old religion, and yet with it all, epilepsy has not ceased to be the subject of conjuration and magic.

Superstition, no matter how degraded, will always outlive faith. The fathers of the church belonging to the first Christian century, fought and struggled in vain against the traditions of heathenism. Chrysostom said that a Christian had better far endure sickness and death than have his health restored and his life lengthened by means of amulets and exorcisms. But the Christians would not listen to this voice, and in the end the Church was forced to make amends. When it erected its places of worship upon the very ground where formerly were temples and sacrifices, and changed the heathen festivals into Christian ones, new methods of supernatural cure were instantly put into practice. Even the kings by God's favor did not hesitate to adopt this sort of accomplishment—not only the most Christian kings of France, but also those of England, until the first representative of the House of Hanover mounted the throne, Catholic and Protestant alike cured scrofula by discourses and sundry calming influences. At that time the disease was called "Kings' Evil," just as epilepsy was termed the "divine disease."

Such obtuseness in regard to traditional superstition may seem astonishing, not to say alarming. It lies, however, deeply imbedded within the human mind. How long has the fear of ghosts at night been kept up, while scarcely anyone dreads spirits in broad daylight? According to the testimony of Signoria Coronedi, people in Bologna burn daily the combings of their hair, to the end that no witchcraft can be perpetrated upon them, and I remember distinctly that when, as a boy, my hair was cut, the clippings were carefully thrown into the stove.

The inhabitants of some of the Malay Islands fear that a magician will have their lives in his power should he take the remnants of their meals and burn them in a peculiar sort of ashes called *Nahak*. Everywhere we find the same childish tricks performed by men in the lower orders of life that they may create fictitious personalities, endow living or inanimate bodies with imaginary powers and trace out the superior force of spirits in purely natural incidents. This is nowhere to be seen so plainly as in the origin and cure of disease, and if the source of various maladies is referred to enchantment, possession or dispensation, it arises mainly in regard to the cure to be effected.

[1] Andrew Jackson Davis, M. D. *Harmonious Philosophy Concerning the Origin and Destiny of Man—His health, disease and recovery.* Leipzig, 1873, p. 93.

[2] F. G. Welcker, *The Art of Healing Among the Ancient Greeks. Bonn,* 1850, p. 95, 112, 151.

[3] *Magni Hippocratis Opera Omnia*, Edit. Kuhn, Leipzig, 1825, Vol. 1, p. 234.

[4] O. Peschel. *Knowledge of Nations.* Leipzig, 1874, p. 274.

[5] Hippocrates. *De Morbo Sacro.* Welcker, p. 587.

The reason can easily be comprehended. While we are familiar with the natural causes of maladies we are still in want of a well organized acquaintance with their natural preceding incidents. By taking an unprejudiced view of the case, we can easily see that even Hippocrates had recourse to nature in curing diseases. Physics, he designated the basis upon which the healing incidents rested, and there can be no doubt that this term was the same to him as is to us the tautological epithet of the "physical nature of man." If you read attentively the part in which he mentions this, you can no longer doubt that he had the whole question of man's bodily formation foremost in his mind. Taken in this sense, the healing powers belonging to the body itself must consequently be natural or physical organic forces.

The idea, however, was in a certain measure a prophetic one. Knowledge at that time was not sufficiently extensive to admit of, or to supply any explanation of it. Even the most favorable and clear sighted observations relating to natural incidents in healing, led to nothing more than a superficial, and to a certain extent, brief conception of the events. This sufficed certainly to establish their situation, and also furnished abundant cause for application of remedies at certain times and on particular parts of the body, remedies which seemed adapted to facilitate the natural course of events, to favor it, or in case it remained concealed, to bring it forward.

There have been numerous attempts to explain all this. One school after the other produced its doctrines, but each one of them was based upon imperfect or voluntary suppositions. Each new step of progress in the knowledge of various occurrences which take place in the human organization overthrew the opinion under consideration and produced another. Of course this did not conduce to strengthen faith in regard to scientific medicine.

It was only during the period of spiritual inactivity when nature's perceptions remained for a long time unchanged as in the early portion of the middle ages, and the Church as well as Medicine adopted natural science in its system of teaching, that medical doctrines gained for themselves the recognized character of stability. It was then that the physician attained aristocratic honors. However secondary schools then arose and dilettanteism pushed forward into existence. So it was at the time of the German revolution, the French revolution and the formation of a new German kingdom.

At no period whatever has mysticism been wanting. A peculiar form of it deserves to be especially mentioned. It is called mystical calculation; its origin lies buried in the most remote practical teachings. Hippocrates himself, observing a country which up to this day is shunned on account of its malarial influence, has established with minute exactness the duration of the feverish maladies which arose from the marshy districts with peculiar regularity. He not only ascertained the precise duration of the fever, but also the days when a decided crisis would appear. The numbers acquired served to denote when the treatment should be discontinued as the critical days, the 7th, the 11th, etc., designated the proper time for the administration of remedies. In this way the calculating system became celebrated, and as it was made a subject of universal contemplation before the days of Hippocrates by the various philosophical schools, we cannot be surprised that those who succeeded them thought to recognize in the theory more than mere expressions concerning the legitimate relation of things to each other.

During the Middle Ages astrology formed a close alliance with medicine, and the constellations occupied the places of the ancient oracles. But even subsequent ages have repeatedly had recourse to conceptions which nearly approach those of the Pythagoreans. Particularly towards the close of the preceding century, discoveries in the departments of electricity and magnetism caused the biological sciences to adopt the theory of polar attraction, a doctrine in which the heterodoxy of animal magnetism, and its companion spiritualism is firmly rooted. In the Pythagorean philosophy, a two-fold existence was supposed to be at the root of everything, and the circulation of this doctrine has resolved itself, so to speak, into the "Great Prophet" of America, according to whose conception Providence is a moving substance formed of positive and negative proportions, and which acts upon matter in different ways through the agency of the number 7.

Among all these attempts to grasp the phenomena in a determined manner, an effort comes to light which is in every way worthy of recognition. It has been shown that the human intellect has no more a universal and spiritual form which can establish the relation and conception of things, than it has a material one. Calculation produces the definite value by which we are enabled to assign things to their proper places. It is for this reason that intricate natural sciences, physics and chemistry partake every day of a more mathematical character. The descriptive natural sciences follow timidly in their footsteps, and even physiology and psychology have already been made to travel over the same road. How then, could medicine escape?

However, the numbers 2, 3, 4, 7 and 10, do not suffice to explain the infinite multiplicity of things, even if the combination of ten numbers serves to account for each calculation. Every reckoning about actual things rests upon observation and not upon inspiration. The more difficult the calculation, the more complex must have been the preceding observation which went to supply the elements of the reckoning. This is true, earnest work, such as no one individual is capable of producing. One workman assists the other, and one generation helps another, not only in transmitting results, but also their aim and object.

It will be a difficult task, nevertheless, for any generation to recognize self-acting forces in numbers. If two objects attract each other it is not owing to the things themselves. And there is no number in existence which possesses healing powers, and no talisman compounded of numbers which possesses active force. The numbers supposed to play an important part in disease only serve to give those versed in art the means by which they may discover the time and duration of the malady and arrange their mode of action accordingly.

But just as Astronomy is incapable of moving the moon or planets by means of numbers, so is the physician unable to produce any effect upon the course of disease or recovery by the same process. Numbers are not remedies, for remedies are actual things, which stand at the disposal of medical art; are actually applicable, and which possess in a certain sense real powers of healing. When we consider them, however, we come to a lengthy and apparently increasing contention which is embodied in medical history in the names of physiologists and technologists. Physiologists are those who seek healing powers within the physical organization itself, while technologists think to recognize them in such means or influences which exist independently of the patient and are directed toward him.

It is true that the physiologist does not altogether despise remedies, but they only serve, in his opinion, to set the organic powers at large. The technologist, on the contrary, intrenches upon the organism. He forces life into artifical conditions. He "orders" and "prescribes" where the physiologist is satisfied with existing circumstances and comes forward as Nature's servant.

Of course a long time has elapsed since the controversy between these two schools was at its height, but in some recent accounts it appears again, not only in specified cases of treatment, but also in a general sense.

Not many years ago blood-letting was a daily occurrence in every hospital, and indeed in almost every private practice. Now it has become so rare that young physi

cians are scarcely acquainted with it. When I was a young hospital assistant I was frequently forced to perform cupping four or five times in one morning. Singularly enough the change came at a time when we were the least prepared for it. In cases of inflammation of the lungs, where the most audacious blood letting was considered an almost irrefragable means of restoring the patient, they began in the Universal Hospital at Prague to observe the natural course of the disease without the application of any remedies. They contented themselves with giving the patients plenty of fresh air, good attendance, greater cleanliness than they were in the habit of getting and strict dietetic surveillance. In the way of medicine, they got nothing, and yet very favorable statistics were obtained. In this way physiology gained a victory over technology, and at the first step reached the highest form—nihilism.[6]

Since then a certain reconciliation has taken place. A firm conviction arose that hospital practice could not merely be influential to private practice—that the hospital, with its manifold contrivances, its order and regimen, possessed provisos and remedies which in a private family, even a wealthy one, could only be imperfectly established, or else not at all—and finally that the nihilism of the hospital physician could not be transmitted to families.

Of course, both physiology and technology will continually enlarge in the future, the more so as experience gains new perceptions and increased power. This, we all know, is inevitable, and the public, which might justly reprove medicine for its scientific changeability, should bear in mind constantly that it is the fate of humanity to be fickle, not only in regard to science, but also every other matter, from the State to the Church. We can only hope that changes everywhere will be made with as much honest intention as they generally are in regard to science.

It would, perhaps, be possible to check trivial fluctuations if people could only agree better as to proper healing objects. This is precisely the point over which scientific men find it so difficult to attain to a uniformi y of opinion. When a physician is called upon to cure he has the case before him, represented by the patient— a unity so to speak. And yet the malady itself gives the impression of another unity. It has the appearance of some strange being which has implanted itself in the individual. It has been not improperly termed a parasitic organism, which lives in or upon the system of the patient. Numbers of times it has been asserted that a strange existence has penetrated into the sick man and "possessed" him. All these ideas unite in the practical task of expelling the disease by driving it forcibly from the body. Is it not perfectly evident that a double existence takes the place of the former unity? Can any conclusion be drawn from such premises, except that the "case" must be regarded as dualistic? If the physician has the patient *and* the disease before him; if he is to separate the one from the other; if the practical endeavor is to act *against* the disease and *for* the individual, can it be a question of a unitarian conception?

Truthfully speaking, such an idea has never properly existed. Even in cases of sickness which were termed rather figuratively universal, it was always understood that a more or less large portion of health should remain undisturbed. It was this remainder that caused "reaction" according to some schools, and led the battle against strange intruders. Paracelsus, in the Middle Ages, expressed these thoughts in the most worthy manner. Let us take up the point and imagine a defensive battle whose seat of action is the human frame. Who are the combatants? On one side we have the disease, in the other the healthy portion. The latter, of course, can go forth with no other weapons of defense and attack than those previously possessed. Where can new ones be found? The means of resistance must necessarily spring from the physical system itself. Thus far the ideas are simple enough. But if we see that the struggle is carried on according to a military principal, that it has a tendency to cure, and that the means of reaching this end are apparently, purposely and systematically chosen and put into action, what power shall we consider the decisive one? What is the leading principle, and where are we to look for it? The generality of physicians say with Hippocrates, it is Nature. But do we not, so to speak, run around in a circle when we first of all call the legitimate formation of the body nature, and then again have recourse to the same term when we wish to explain how this arrangement resolves itself into a systematic unitarian course of action? Have we not a substance to deal with in the first case, and a force in the second—and an organized force too, a force with designs and purposes—a species of spirit in fact? Paracelsus was firmly convinced on this latter point. He designated the decisive power the *Archæus maximus*, which corresponded to *spiritus rector*, or leading spirit.

Georg Ernst Stahl, the celebrated clinical lecturer, in the beginning of the past century, went a step further. He set up the soul itself, the *anima*, as the decisive principle. But at that time the philosophy of the unknown was not yet invented, and it was difficult to demonstrate that the hitherto thinking and conscious soul could here work in an entirely unconscious manner, and yet be systematic withal. It was also extremely hard to trace the diseases of cattle, the *morbi brutorum*, or the maladies of plants to a soul, if we did not wish to run the risk of losing the conception of the term by this extensive generalization.

Toward the close of the past century we became more and more inclined to admit the existence of an organic force secondary to the soul—some called it vitality, others natural healing power. Those inclined to the former opinion endeavored to unite a given relation of the healthy organism with an effort directed upon itself. Those who adhered to the latter idea were firmly convinced that a peculiar regulating force existed.

At all events, the much sought for *unity* was driven further and further into the background by the sudden appearance of these new forces. There was no longer merely a *dyas*, but a *trias*. The disease, the remaining healthy portion of the body, and the particular force which ruled it. And no matter what special term was employed to designate the latter, it always partook of a distinctly spiritual character. Many attempts were made to reduce it to a scientific quality; to construct it according to a physical dynamic system; to interpret it as a particular form of electricity or magnetism.

However, as soon as the matter was entered upon seriously, and all the systematic plans and workings investigated, natural science became instantly transformed into a spirit.

Nevertheless, assistance was frequently deemed necessary. The course of the struggle was observed more minutely, and if it was found to be too weakly conducted either by vitality or natural healing force, endeavors were made to strengthen both, or at least to incite them to greater activity. But if the battle was found to be sustained with more force than necessity required, pains were taken to moderate and reduce the action. Thus arose a classification of conditions pertaining to disease—asthenic, sthenic and hypersthenic, names derived from *sthenos*, signifying strength.

It would lead us entirely too far from our course, should we attempt to expound the history of the various healing systems. It may suffice to say that every one of them, to use a common expression, has left its traces behind, and that an acute eye can easily detect them. According to our present ideas all these systems rest upon an erroneous conception of life and disease, inasmuch as

[6] *Archives of pathological anatomy*, 1849, Vol. II., p. 14.

they endeavor to attribute a more or less personal significance to each of these terms. The perception thus becomes figurative and typical.

Modern medical science has utterly renounced this tendency to personification, where the pre-supposed force does not correspond with an actual demonstrable body. It further separates simple forms from compound ones, although, according to the mode of observation they may possibly produce the impression of unity. For instance, the human organism appears to be a compound form, although we may correctly apply to it a personal expression. Each particular cell can be interpreted as a personality, for they are all self-existing and self-acting, and their power emanates from their own construction — their *physics*. In this sense the human body is not a unity in the strict *material* meaning of the word, but on the contrary a plurality, a collective form, and in a certain degree, a state. There likewise exists no one force which rules it and establishes its action, but on the contrary, a coöperation of many forces which are inseparable from the living element. Even the greatest phenomenon in human life, the spiritual I, is therefore no steady, immovable capacity, but a very changeable one.

If the human organic structure appears to us a unity it is chiefly due to three circumstances: First, in the construction of the vascular system and in the blood circulating through it, there is another perfectly accorded system which pervades the entire body, effects the material intercourse of the various substances, and constitutes a certain dependence of the parts upon the blood. For a long time, therefore, people looked for the source of life merely in the blood, and endeavored to explain all the incidents pertaining to disease and cure by means of the blood alone. When it appeared to be impure it was refined with inappropriate substances. When there was apparently too much or too little, it was drawn off, or attempts were made to produce it. In the second place, in the formation of the nervous system to which man's highest powers are attached, namely, the intellectual, we find an organization extending throughout the entire body, converging to the brain and spinal marrow, and which on one side is qualified to adopt outward impressions and conduct them to the great centre, while on the other side it possesses the capacity to eject any impulse directed upon other portions of the body by causing them to make particular assertions of activity or else to limit them.

Diseases such as fever, for instance, can only become intelligible by referring the great number of collected phenomena which come under this category, to the nervous system.[7] What wonder then that there is continually a fresh attempt to explain disease and cure by means of the nervous system?

But there is still a third point. This is the enormous mass of tissues of which the body is built up. The compound construction of countless numbers of cellular elements which are organized in the most varied manner, and are capable of producing the greatest diversity of results. Many of them, such as the muscles, appear in a high degree to be simple bearers of strength. The blood would be an immovable mass if the muscles of the heart and vessels did not circulate it mechanically. Other tissue formations, as the glands, superintend various things, the act of secretion, for instance, which represents a no less declaration of force. But each of these regulations, every one of these so-called organs is again a plurality compounded from endless elementary organisms, the cells. And when we see that the nervous system is just as complex, that the vessels, the heart and the blood are likewise compound combinations, it is well proved that every observation which does not apply to a compound element must be external and superficial.

If such a conception upon first sight results in a detachment of the body, a total breaking up of the perception, a further contemplation will show that these innumerable elements do not exist in juxtaposition. Accidentally or indifferently, they belong to each other on account of their common descent from a simple element which insures a certain original resemblance and relation among themselves just as there is among the descendents of one family.

This is the "divine necessity" of Hippocrates in its modern form. It does not merely assume the material of all elements to be one organism, but it also concludes that it must form certain combinations by means of which the effect of the different elements through each other produces a legitimate arrangement of the general principles.

Such organizations undoubtedly occur in the vascular and nervous systems, and they exist also in the great masses of superfluous tissues. For even as the vessels and nerves influence these latter, so on their side they influence them. Thus arises a reciprocity of effect which can be beneficial or otherwise, according to circumstances.

As long as the effect is beneficial, so long will the organization appear to be in harmony. And we can experience it in our consciousness as a sensation of well-being. If the effect should be injurious on the contrary, we say disease has entered the system, and we experience a feeling of discomfort. These sensations do not relate solely to bodily conditions, but to those of the mind, also. There is moral as well as physical indisposition.

In a figurative sense, we might say *equilibrium* instead of harmony, and *loss of balance* instead of discord. In many cases such designations would have an actual significance. The distribution of the blood is arranged to a certain extent, according to simple hydro-dynamic principles. An increase in one part necessitates a decrease in another. The electricity existing in the nerves can be interpreted in a purely physical sense. Here are tensions and accumulations, there evacuations and discharges of electricity. Even the usual incidents pertaining to the growth of the tissues provide us with numerous examples. If one part increases in strength, another diminishes. A suitable instance of these antagonistic phenomena is given in the difference of incidents pertaining to growth between the male and female sexes.

From these remarks we alresdy see that any disturbance of the harmony or equilibrium does not merely affect the common sensations, and therefore the nervous system, but also other parts of the body, and it can be readily understood that one disturbance will act upon this portion, and another upon that, etc.

All the parts do not stand in equal relation to each other, and those whose mutual dependence is the closest will, of course, be the soonest affected, while the others will be influenced in a lesser degree or else not at all. We designate the closer relationship as *sympathy*.

All these connections exist uniformly in sound, healthy bodies, and in order to explain them, we have no need to refer to the soul, vitality, or any other special spiritual force. When a diseased disturbance of the equilibrium occurs, they represent what we call *organic healing power*.

In order to obtain a full comprehension of this it is not actually necessary to say much concerning the healing itself. The theoretical discussions which have taken place in regard to this point, and the practical inferences derived from them, have often become very much confused inasmuch as entirely opposite relations have been drawn together by means of them.

The old word medicine, which is almost synonymous with our modern term therapeutics, led to the misunderstanding that the entire practical energy of the physician should be directed to one particular point of the bodily condition inasmuch as his chief task is to cure. A closer reflection will show, nevertheless, that this is by no means the case.

Only a certain portion of medical power, although it

[7] Virchow. *Fever. Four Discourses upon Life and Disease.* Berlin, 1862, p. 129.

may be the greater part, has reference to the curing of disease. Important branches of medicine allude to circumstances of sound health supervised by the physician in order to prevent disease. Every year our activity in this respect increases.

Besides the removal of the various causes of disease there is another cure which we designate as the *curatio causalis*. A foreign body such as a bullet, a glass splinter, etc., penetrates into the organism and remains there. Frequently, if not always, the removal of this body is the proviso of a cure. This of itself, however, is not sufficient, for the cohesion through which the foreign body passed must first be united, and the natural connection re-established, before the actual restoration can be acknowledged.

Very often restoration is spoken of when the case in question consists merely of a disturbance or a simple deficiency. If a person breaks his leg he is not ill. He cannot walk, of course, and an actual malady can proceed from the fracture if the surrounding parts become inflamed and the nerves excited. But the fracture itself is no illness, although it may become the cause of one. In spite of this, however, the sufferer always hopes to be "cured" by the physician.

Now it is unquestionably true that the same principle of observation cannot be applied to all such cases, otherwise we should become hopelessly embarassed. A broken knee will never set itself; therefore the physician is not to rely at all upon nature but simply upon his own skill; but he does not occupy himself with the phenomena by means of which the fracture will be re-united. That happens by itself. The medical influence in question is certainly technological. It is by means of force that the physician brings the pieces together in a position which as nearly as possible corresponds to the natural one. It is by means of force that he holds them thus. But all that is not a cure, but merely the stipulation for one. The broken part finally grows together in a very bad shape, and the re-establishment of the connecting portions occurs only with a very unfavorable position of the fracture. Nature in this case works most powerfully.

Every restoration of a broken bone is also physiological, and the physician only endeavors to let it occur undisturbed and under the most propitious circumstances. This "only" is of very great importance to the patient, for a fractured bone which heals crosswise or crookedly can infringe upon the use of a limb for life. But when we come to investigate all the theories of healing we must remain firm in stating that recovery from fracture is not caused by the physician. *The cause of the cure is due to the surrounding tissues.* They produce a new tissue, which forms over the scar.

We now come to *actual diseases*. They are not mere disturbances or yet definite conditions. An actual disease is an incident, also a succession of conditions, one preceding from the other and affecting vital parts. No lifeless object, no dead body ever becomes subject to disease. An animal or a plant can become diseased, but only while they are alive and only in such parts as are endowed with life. Therefore, every disease is a demolition to sound health, for the same part cannot at once be sick and well. Disease is also an incident pertaining to life. We call those incidents disease which deviate from the typical form of life and which are at the same time affected by the danger to which they are exposed, for disease strives towards death, be it local or general, and, consequently, it struggles against health.

If disease is incidental to life, it must be allied to certain living portions. Therefore we say the disease is "seated," and it is frequently one of the physician's most difficult tasks to discover precisely where this seat may be. But I must correct myself. In many cases the disease is located in several places. If a person has inflammation of the lungs, he usually has a violent fever in addition. In this case the inflammation is situated in the lungs and the fever in the centre of the nervous system —two entirely different places. Is all this one disease? Even at the beginning of the present century inflammation of the lungs was put under the category of fevers. Now it is considered as local inflammation. Still, it is the fever principally that is treated, while the inflammation is left to Nature. I will not enter into the fact that among many people who suffer from inflammation of the lungs, the stomach and kidneys also become diseased. What I have already said will suffice to show that the mere investigation made to discover the location of the disease leads us from the idea that it can be a unity. Unity only exists in so-called imaginary maladies. It is entirely figurative, a simple fancy, an abstract. In reality, most diseases are distinct pluralities, some existing in which the number of locations is countless.

It remains further to be said that in reference to diseases the word "cure" has many significations. If the term in plain language means wholeness without injury, it should designate the entire and complete re-establishment of the condition. Such an interpretation as this speaks badly for technology. If one has a tumor on the knee and the leg is amputated, curing denotes none the less a complete reestablishment. But it does not always agree with physiology either.

There is scarcely a single form of inflammation of the kidneys which admits of complete restoration; hardly one example of inflammation of the brain which does not always leave certain defects. These diseases therefore, are cured but imperfectly, and yet we may say the patients are quite restored because in spite of the deficiencies, new relations and connections take place in the body which cause the equilibrium of the actions performed.

As an example of the most perfect cure that we know of, I might mention inflammation of the lungs. Although it happens that in the course of a few days five, eight or even ten pounds of matter are deposited in the lungs through which the air inhaled should penetrate, we see, nevertheless, that again within a short time the entire mass is loosened and gradually disappears. This is the consequence of mere natural circumstances. But it requires only trivial aggravations, insignificant want of foresight, slight renewal of deteriorating causes, to interrupt this natural incident; then no relief can occur. On the contrary, the masses of matter remain firm like dead material; they break in pieces; the tissue surrounding them becomes impaired and thus the first step is taken toward that insidious occurrence called consumption. Therefore, the timely advice of a careful physican is very important even if he does not cure, and consequently no one should confidently imagine that all can be satisfactorily arranged independently of him.

Every incident of disease arises either from a defective nutrition or formation, or else from some disturbance of the local actions. A compound disease frequently includes all of these reasons at once. Defects of nutrition and formation are generally classed under the category of *organic imperfections*, because in both cases local alterations take place in the organism. For this reason the equalization of the disturbances occurs generally very slowly. The defects can only be removed gradually, and the normal condition established by degrees. Functional imperfections on the other hand can often be removed in a moment, because the inward construction does not change and the local action is altered merely by unusual excitation or oppression. The more the disease is confined to functional blemishes, the quicker it can be removed.

In any case whatsoever, the cure is obtained by complete restoration of the bodily harmony. It consists of a balancing and regulation of the disturbed relations, and indeed, an equalization through inward bodily resources. The healing powers are situated in the vital portions of the organism. These parts nourish themselves, and produce adequate conditions. They bring forth actions

which serve to direct, relieve, and repair certain defects of the equilibrium. Even when the physician's utmost power is exerted, when the part in question is cut off or destroyed, then also, restoration of the bodily equilibrium is necessary before any tolerable result can be produced. Also, when the healing powers remove certain imperfections, when an acid is neutralized by an alkali, or when a dormant faculty is roused into fresh activity by any excitation, the cure can only be perfect if the natural relations return again, or else if new ones are formed. Every outward effect is only a means by which to lead the inward formation of the body to free and regular action.

No physician can trust wholly to nature, but neither can he produce by art that which takes place naturally in the body. That is the work of the organic healing powers. Every medical man must rely upon their efficiency, but at the same time he has no right to sit idle with his hands in his lap in consequence. On the contrary it is frequently necessary to employ the most forcible interference in order to regulate the action properly. In particular diseases, how much nature is able to perform, and how much the physician is compelled to do, can only be ascertained by personal experience, and can be determined *a priori* by no theory. On the other hand, how far, in certain cases, medical treatment must extend, and how far the natural course is to be influenced by the physician, is not merely a question of experience, but frequently one of scientific value, which only an educated and cultured physician is capable of undertaking. Experience alone, in the medical world, produces only adventurers who perhaps may succeed now and then, but for whom self-reliance is always a risk. Such experience as is led and regulated by Science alone is capable of removing all barriers, and able to designate the realm in which nature and the physical organic forces have the supreme command.

Separation of Cadmium and Zinc.—In a memoir inserted in the *Annales de Chimie et de Physique* (Series 4, vol. 30, p. 351), M. Riche described a process for the determination of zinc, either by the decomposition of the acetate or by the electrolysis of the solution containing sulphuric acid. Several researches on the same subject have since been published by different authors. MM. Beilstein and Jawein, whilst confirming the results of Riche, employ the following process:—The nitric or sulphuric solution of zinc is mixed with caustic soda until precipitation ensues, and then with potassium cyanide till the precipitate is re-dissolved; the electrolysis is then effected with four Bunsen elements. The determination of cadmium has been effected by the same chemist under the same circumstances by means of the current from three elements. M. Millot has recently given a process for the determination of zinc by electrolysis of a solution of this metal in potassa. M. Edgar Smith obtains a precipitate of metallic cadmium by passing a strong current through a solution of the acetate. These procedures have the defect of not serving for the separation of cadmium and zinc, as the two metals are precipitated simultaneously. They may be separated as follows:—The solution containing the two metals in the state of acetates is mixed with 2 or 3 grms, sodium acetate, and a few drops of acetic acid. The current from two Daniell elements is then passed through the solution as described by M. Riche in his memoir. The cadmium alone is deposited in a crystalline layer at the negative pole, the zinc remaining in solution. The process requires the aid of heat, and requires three to four hours for quantities of 0·180 grm. to 0·210 grm. cadmium, and as much zinc. The deposit is effected in the crucible, and the liquid is then drawn off and serves for the determination of the zinc, according to M. Riche's process The deposit is washed first with water, then with alcohol, dried, and weighed. If the zinc and cadmium are present as sulphates the author recommends precisely the same method. Or the sulphuric solution may be mixed with ammonia and ammonium sulphate.—A. Yver.

MANUFACTURE OF YEAST WITHOUT ALCOHOLIC FERMENTATION.

A method of manufacturing yeast without alcoholic fermentation, and without the formation of subsidiary products has been patented in England by Dr. J. Rainer, of Vienna. The process is carried out in the following manner:—The vegetable albuminous substances in the corn cereals or other vegetables, or such refuse of industrial establishments as bran cornings, malt residuum, gluten, and the like, are extracted with the aid of from 15 to 20 parts by measure of water, made slightly alkaline. They are then either peptonized by adding an excess of lactic acid (about 4 per cent.) or mineral acids (about .25 per cent. of phosphoric acid, or about .4 per cent. of either sulphuric acid or hydrochloric acid) at a temperature of from 55 to 100 degrees Fahrenheit, or they are at once macerated in dilute solutions of the above acids and simultaneously converted into peptone. A portion of the albuminous substances (from 5 to 10 per cent. of the total weight) in the dried cornings will be already transformed into peptone by the process of vegetation. The albuminous substances in cereals, maize, or other vegetables, and in bran and malt residuum are transformed into peptone by the addition of diastase. In order to effect the conversion it is sufficient to add to one part by weight of the albuminous matter when dry, one part by weight of dry malt, or five parts by weight of cornings. As stated the liquid in which the albuminous matter is to be transformed into peptone must contain lactic acid (4 per cent.), phosphoric acid (as much as .25 per cent.), sulphuric acid or hydrochloric acid (about .4 per cent.), because the presence of an acid is absolutely necessary in the process of converting these substances into peptone.

A temperature of about 100 degrees Fahrenheit is the most suitable for the conversion of the substances into peptone, and a period of from 18 to 20 hours will be sufficient to effect it. It may, however, be also carried out at lower temperatures during a correspondingly longer time. In working cornings it is superfluous to add malt, because the diastase contained in the cornings is more than sufficient for the process of conversion into peptone. Therefore it is only necessary in this case to use one of the above-named acids in the proportions given. The slimy pectates contained in the cornings as well as in other materials are dissolved by the combination of diastase and acids. When the preparation of pure peptone is required the pectates may be separated by an endosmotic apparatus or dialysator, in such a manner that the peptone is dialysed through proper membranes in water, while the gelatinous pectates remain as a residuum. The acids are neutralized by means of soda, or by saturating the liquid with basic phosphate of lime. The prepared peptone liquid, with or without a percentage of sugar, may be shipped as a saleable article, or it may be delivered in a dry state, or as a syrup or extract obtained by boiling the liquid down in a water bath, by steam, or preferably in a vacuum. The liquid containing peptone may be separated from solid matter (hydrocarbons, vegetable fibre, or the like) by simple extraction, maceration, or pressure, or by centrifugal action, or it may be carefully cleaned by filtration or settling. It is advisable, however, before cleaning by filtration or settling to naturalize any acid present by means of soda, or to saturate the liquid with basic phosphate of lime, the latter being preferable because the phosphoric acid required by the yeast is thus abundantly furnished to it. In order to start the growth of yeast, gelatinized starch is added after being transformed in the usual way into dextrose by boiling with an addition of mineral acids. In the place of starch thus prepared an addition may be made of maltose, molasses, or sugar mixed with beer-yeast or compressed yeast. The amount thus added should correspond to the percentage of pep-

tone in the liquid, being one-half of the dry weight of the peptone. The hydrocarbons should, however, always be only from .5 to 1 per cent. of the weight of the entire liquid, and should even then serve exclusively for the formation of the walls of the cells of the yeast.

The vegetation of the yeast will take place most satisfactorily at temparatures varying from 57 to 64 degrees Fahrenheit. At a higher temperature losses may easily occur by reason of the partial conversion of the sugar used into coagulated acid or into alcoholic fermentation, instead of furnishing the yeast with substance for cells. The yeast is either propagated, as is the custom in Holland, in shallow vessels in which the depth of liquid is about five inches, so that a sufficient quantity of atmospheric air has access thereto; or it may be better and more safely effected in vats made of wood, glass, masonry, cement, or other suitable material, into which atmospheric air is conducted by suitable distributors through tubes or pipes by means of blowers or compressers.

Instead of atmospheric air alone it is more advantageous to use air containing an increased amount of ozone or of oxygen partially converted into ozone. The latter is prepared by successively adding hydrogen dioxide to the propagated liquid. The percentage of ozone in the air is increased by means of phosphorus, or by causing it to pass through a closed vessel in which permanganate of potassa is mixed with the necessary quantity of mineral acid. The air thus enriched with ozone is then allowed to pass into the propagating liquid.

The growth of the yeast will be completed within from 6 to 8 hours after every sufficient addition of dextrose, maltose, or other material, according to the density of the propagating liquid used, the temperature of the latter, and the amount of the ozone in the air. The percentage of peptone of the mass may amount to from 1 to 2 per cent. or more of its weight, while only from one-half to one per cent. of dextrose or other hydrocarbons is added at each time, in order to be sure to prevent the formation or coagulated lactic acid or alcoholic fermentation.

When the entire amount or bulk of the dextrose or other sugar added to promote the growth of the yeast has been consumed after from six to eight hours, a further quantity thereof, say, from .05 to .10 per cent. is added. The peptone may also, after having been consumed, be added in portions, or may be allowed to flow in gradually and continuously. The same propagating liquid made by successive replacement of the matter consumed remains in use for weeks or months, unless it is rendered impure by other substances, or by subsiding fermentation is made unfit for further use. In the same manner as the materials necessary for the propogation of the yeast are added the yeast produced may be successively withdrawn, and only the yeast suspended in the liquid remains behind as the germ for the ferments of alcohol to be afterwards formed. The yeast is obtained either by skimming it from the surface of the liquid or by separating it from the propagating liquid by filtration, or finally by gathering it after tapping the vats from the bottom upon which it is deposited in a compact layer. In working on a large scale it is advisable to place the vats in terraced batteries in order to effect the transfer of the propagating liquid from one vessel to the other with facility. In order to produce yeast as free as possible from subsidiary ferments the propagating liquid may be prepared in a more dilute state, that is to say, with a percentage of peptone of only from .75 to 1 per cent. The hydrocarbons (dextrose, maltose, or the like) may also be added in smaller quantities, for example, as a first dose about .33 per cent. and then every 3 hours about .05 per cent.

The greater part of the peptone present will then be transformed into yeast in from 12 to 15 hours, a sufficient supply of pure air, if necessary, conducted through sulphuric acid or oxygen containing ozone, being provided, and the entire process being carried on at a temperature varying from 54 to 63 degrees Fahrenheit. The whole liquid is then cooled by a suitable apparatus, or by adding cold water or ice; the best temperature being from 45 to 50 degrees Fahrenheit. Within from 36 to 48 hours the yeast obtained will settle on the bottom of the vat. The propagating liquid may be allowed to flow away. The yeast obtained by this improved process is purified and condensed in the usual manner, but in order to increase its durability phosphate of lime amounting to from 4 to 5 per cent. of the total weight of the yeast to be made may be added before compressing it.

Experience has shown that from 250 to 300 parts of pure and active compressed yeast may be obtained from 100 parts of pure peptone. For the growth of that quantity of yeast only about 200 parts of dextrose or sugar are required.

MICROSCOPY.

We have received the February issue of the Journal of the Royal Microscopical Society, now edited by Mr. Frank Crisp, one of the secretaries of the society. It contains a valuable and interesting original paper, with two full-page illustrations, and the proceedings of the R. M. C. A summary is also presented of current research in those departments of science, depending upon the use of the microscope for their advancement. The amount of information thus gathered may be estimated from the fact that the present number is a volume of one hundred and seventy-two pages. The Journal appears bi-monthly, and costs one dollar (4*s*.) for each part.

The President of the Royal Microscopical Society announced that a fund had been provided for the presentation of two gold medals annually, without regard to nationality—one for the person who should originate any important improvement in the microscope, or any of its accessory apparatus, or in any other way eminently contribute to the advancement of the microscope as an instrument of research. The second gold medal was to be awarded "in respect to any researches in any subject of natural science carried on wholly, or in a great part, by means of the microscope, or of the recipient having in other ways eminently contributed to the advancement of research in natural science in connection with the microscope."

The two medals were to be known respectively as the "Microscopical" and "Research" medals of the Society. For reasons which are not stated, the offer of this fund was declined by the Council of the Society.

The war of Apertures of Microscope Objectives has again broken out in the R. M. S. In this instance Mr. Shadbolt was the aggressor, who claimed that his paper demonstrated beyond dispute the following facts, viz.:

"That a dry lens can have as large an 'angular aperture' as an immersion one, and that the assumed difference of aperture between dry and immersion lens does exist."

"That no lens can have an 'aperture' of any kind which exceeds that of 180° angular in air."

"That, consequently, the table of 'numerical apertures' published on the cover of the *Journal* of the Society is erroneous and misleading, and should at once be discontinued."

In reply, Mr. Crisp asserted that Mr. Shadbolt was in error, and the victim to a misplaced confidence in a fundamental fallacy, viz., "the supposition that equal angles in different media, as air and oil, are optically equivalent."

A correspondent, who is an authority on this subject, will offer an opinion on this matter. We believe, however, that Mr. Crisp is correct in his views, and that the society has exercised a wise discretion in putting a stop to a discussion, which had become wearisome and unprofitable.

Mr. Crisp showed how a few moss-grown English microscopists had persistently refused to countenance

the use of immersion objectives, which are now in universal use, and accepted as a valuable improvement.

The use of oil was suggested by Amici, as far back as 1844, by Oberhauser in 1845, and Wenham in 1855 and again in 1870, and only admitted in practice in 1878, so that it appears to have required 34 years to convince microscopists of a fact, that might have been settled in a week and this due to "persistence in a fallacy." Such being the case it is surely time for these fallacies to be shelved, and we are glad to find the R. M. S. has taken such a view of the case.

FLUORESCENT BODIES.

If we put some common paraffin oil, or a solution of sulphate of quinine, into a glass tube or other suitable vessel, and then look through it, the liquid will appear quite colorless; but if we allow the light to fall upon it, and then view it at a little distance and at a certain angle, some parts of the liquid will present a delicate sky-blue tinge. The effect in the case of quinine is heightened if the source of light is burning magnesium wire.

The large number of substances belonging to this class are termed fluorescent bodies, because they exhibit phenomena similar to the examples above given. The term itself, however, was suggested to Prof. Stokes by a particular kind of fluor-spar which shows this property.

Again, if we cause a room to be darkened, and allow only blue light (*i. e.*, by covering a hole in a window-shutter with cobalt-blue glass) to fall upon a glass vessel filled with water which has been standing some minutes, on floating a strip of horse-chestnut bark upon its surface, in a few moments a stream of bluish grey fluid (æsculin) will be seen slowly descending from the bark, hanging, in fact, like a bunch of barnacles from an old ocean waif. Of if, under the same arrangement of light, or by using even more powerful absorbents of the ordinary rays (such as a solution of ammonio-sulphate of copper or one of chromate of potash), we look at a piece of what is commonly termed canary glass—*i. e.*, glass colored with an oxide of the metal uranium—it will be seen to glow as it were with rich greenish yellow rays, just as though it were itself a source of light; or if we take a solution of a uranium salt (the normal acetate) the phenomena are very striking when examined under the same conditions, and still more so by the electric light. But the salts of aniline—a substance which is the parent, so to speak of mauve, magenta, and other brilliant colors—are singularly rich in exhibiting these effects.

A very beautiful experiment may be performed with the aniline red ink now so commonly in use. It affords, at one and the same time, an admirable illustration of Prof. Tomlinson's submersion figures and of the phenomena under consideration. If we take a long cylindrical glass vessel, or one with parallel sides, fill it with water, which is allowed to settle, and then gently deliver a drop of the red fluid to the surface, the drop begins to contract, and slowly from its centre descends in the form of a tube; the denser parts of the coloring-matter presently form a thick circular rim at the end of the tube,—but this is only for a moment, for a wavy edge appears upon this rim, then expands into a triangular parachute with a thickened edge, and from the extremity of each corner two or three smaller tubes descend; these in like manner pass through the same phases as the parent stem or tube.–*E. R. Hodges (Journal of Science, London.)*

INTRA-MERCURIAL PLANETS.

A collection of the observations published in the report of the Total Solar Eclipse of 1878, will give, perhaps, the best idea of the present state of the question of the discovery of Vulcan and other planets revolving within the orbit of Mercury; and it may be of some interest to present the matter in the form of a chart showing the ground covered by different observers, who, during the time of totality, devoted themselves to the search for such bodies. For this purpose, the space swept by the six observers, Newcomb, Hall, Wheeler, Bowman, Todd and Pritchett, has been indicated by different shading on the accompanying chart, which is merely a copy of that prepared by Prof. Hall for the use of observers of the eclipse, and published with the instructions issued from the United States Naval Observatory.

The two objects, "*a*" and "*b*," discovered by Prof. Watson, and thought by him to be planets, have been indicated upon the map thus : ⨀. The two discovered by Swift, also announced as intra-mercurial planets, have been marked thus : ⊗.

Swift's two stars are described as equal in brightness, of about the fifth magnitude, and 8′ apart; on a line with the sun's centre. Each had a round red disk, and each was free from twinkling. The object farther from the sun was at one time thought by Swift to be ϑ Cancri, and the other a new planet. The diameter of the field of view was 1.°5.

Watson's star, "*a*," is described as being "between the sun and ϑ Cancri, and a little to the south;" of a ruddy color and about 4th magnitude, or fully a magnitude brighter than ϑ Cancri, which was seen at the same time. The star, "*b*," was also of a ruddy hue, and is given as the 3rd magnitude.

Watson used an aperture of 4 inches; magnifying power of 45 diameters; Swift, an aperture of 4.5 inches; power of 25 diameters. We see by inspecting the chart, that the place of one of Watson's stars (that of which he was the more certain) was covered by Wheeler with a 5-inch aperture; power 100; by Pritchett, 3.5 inch aperture, power 90; and by Bowman with a 3.5 inch aperture and power of 30 diameters. The place of Swift's two stars was examined by Bowman and Wheeler, and one of the stars appears just in the corner of Pritchett's sweep. Finally, the whole ground was covered by Todd with a 4-inch aperture and power of 20.

Of these observers, Wheeler and Pritchett possessed telescopes with optical power at least equal to that of Swift, or Watson, and Bowman's glass was of sufficient power to show any object as large as the 5th magnitude,—but nothing, not already upon the chart, was found.

This should be borne in mind, however, that several of the observers were enabled to make but very hasty sweeps,—not devoting so much of their attention to the subject as Watson did, and, indeed, at Mr. Todd's station clouds interfered seriously with the work. And, on the other hand, it appears that Prof. Watson devoted a large part of his time to sweeping on the east side of the sun.

A glance at the chart will show that Watson's stars have about the same relative positions and magnitudes as ϑ and ζ Cancri, and that Swift's stars as far as relative position is concerned, resemble closely d^2 Cancri and B. A. C. 2810, or the pair of stars similarly placed on the other side of the sun. The probability of an error in pointing the telescope, which would account for such a misidentification as has been suggested, has been thoroughly discussed by Dr. C. H. F. Peters in the *Astron. Nach.*, No. 2253, p. 323, and Dr. Peters' paper has been answered by Prof. Watson in the next volume, *Astron. Nach.*, No. 2263, p. 101.

It is not the intention of this article to consider again the question of the identity of the stars seen by Watson and Swift, but merely to point out the evidence upon which the discovery of "Vulcan" rests, and to call attention to the fact that the existence of an intra-mercurial planet is not yet admitted by the majority of astronomers of the present day.

BOOKS RECEIVED.

A MANUAL OF ZOOLOGY for the use of students, with a general introduction on the principles of Zoology—by HENRY ALLEYNE NICHOLSON, M. D., D. Sc., Ph. D., etc., Professor of Natural History in the University of St. Andrews. Sixth edition, revised and enlarged,. William Blackwood and Sons—Edinburgh and London, 1880.

This Manual of Zoology has become so fully recognized as one of the most complete and reliable guides to a knowledge of this subject, that but few words are necessary in giving notice of the issue of a new edition.

The study of Zoology is constantly bringing new and interesting facts to the surface, hence the necessity for frequent editions of manuals treating on the subject, to keep pace with discoveries. Professor Nicholson has availed himself of the present opportunity to thoroughly revise his work, and bring forward arrears of facts which have accumulated during the past two years, and in accordance with the views of many distinguished naturalists he has raised the order of ***Echinodermata*** to the rank of a sub-kingdom. This alteration necessitates the abandonment of the ***Annuloida*** as a sub-kingdom, and the reference of the Scolecida to the Annulosa.

Professor Nicholson forestalls criticism for such action by candidly admitting that this arrangement is far from being wholly satisfactory, but asks that it may be provisionally adopted as the best under the circumstances, taking into account our present knowledge.

A number of excellent illustrations have been introduced in the present edition, and the student will now have the benefit of over 450 wood-cuts.

The general plan of this book is admirable, and following each chapter is a list of the best works and memoirs relating to the animals belonging to each sub-kingdom.

There is one feature of this work which in our opinion gives it a special value to students, and that is an excellent glossary of about 1000 words. The index is also ample and carefully arranged.

The present work of Professor Nicholson is the latest and best Manual of Zoology, and we recomend it strongly to those interested in such studies.

LIFE ON THE SEASHORE, OR ANIMALS OF OUR COASTS AND BAYS, with illustrations and descriptions. By JAMES H. EMERTON, author of Structure and Habits of Spiders. Naturalists' Handy Series No. 1. George A. Bates, Salem, Mass., 1880.

This charming little work is the first of a series of handy books suitable for amateur naturalists, a class now happily on the increase.

The author has provided a pleasant companion which should be in the hands of all visitors to our coasts, ensuring a never failing fund of amusement, leading insensibly to one of the most delightful of scientific studies.

Mr. Emerton states "I have tried to give such explanations of some of our common animals of the New England coast as have been often asked for by persons little acquainted with zoology, and to give such directions about collecting and observing them as have been found useful to students who come to the shore for a short time in the summer to study animals that they before knew only from pictures."

The book is divided into four parts, treating separately animals which are found "between the tides," "near low water mark," "surface animals," "bottom animals." The reader will find this an excellent arrangement. We find above one hundred and fifty excellent wood cuts, which faithfully represent the objects described in the body of the book; the sensational and misleading illustrations to be found in a somewhat similar work find no place in this volume. We can therefore recommend Mr. Emerton's work as not only a reliable guide, but one which will create a healthful desire for knowledge in those who are so fortunate as to possess it.

CHEMICAL NOTES.

CONTRIBUTION TO A KNOWLEDGE OF SAPONIFICATION OF FATS.—The name fat is generally applied to a mixture of the tri-glycerides of palmitic, stearic, and oleic acids. As regards the animal fats this assumption has been in all cases verified, but the vegetable fats display certain not un important deviations. J. König, J. Kiesow, and B. Aronheim, in saponifying vegetable fats, obtained invariably less glycerine than is required for forming the glycerine-ethers of the fatty acids—a fact pointing to the conclusion that free fatty acids must be present, since the quantity of cholesterine occurring in the plants is too small to combine with the fatty acids. For saponification, potassium and sodium hydrate were used along with the other basic oxides, the latter substances being considered equal in value to the former, the only difference being that the products in the one case are termed "soaps," and in the other "plasters." It was assumed hitherto that the tri-glycerides, like other ethers, were completely decomposed by the above named ethers into salts of the fatty acids and glycerine, and that equal quantities of glycerine were obtained in all cases. For the saponification of fats and the separation of the products, J. König had proposed a process which consists essentially in treating the fat operated upon with an excess of lead oxide in presence of water at 90° to 100°. Dr. von der Becke, when attempting at his request to saponify cacao-butter in this manner—in order to discover a process for detecting the sophistications of this product—found that it could not be saponified with lead oxide, at least not in this manner. It was found on further experimentation that the quantity of glycerine obtained on saponification with potassium hydrate was in all cases considerably the highest. In the easily saponifiable fats, butter, lard, and olive oil, the difference was found less manifest, but it was much more distinct in those which are hard to saponify. Cacao-butter and tallow, if saponified with lead oxide, yield scarcely traces of glycerine. A mixture of an easily saponifiable fat like butter with cacao-butter gave the same quantity of glycerine as if butter alone were employed. It is possible that the reaction when once set up may extend itself. Hence it appears that in the case of some fats the method of saponification with oxide is not trustworthy, and that when the accurate determination of the proportion of glycerine in a fat is required, the saponification must be effected with potassium hydrate.

CONTRIBUTIONS TO THE CHARACTERISTICS OF THE ALKALINE EARTHS AND OF ZINC OXIDE.—The alkaline earths and zinc oxide if their hydrates, carbonates, and nitrates are heated to complete decomposition, are obtained in the following specific gravities. Lime is obtained amorphous from the hydrate and carbonate, but in regular cubic crystals from the nitrate; in either case of the sp. gr. 3.25. Strontia is obtained from the hydrate and carbonate amorphous, and of sp. gr. 4.5, but from the nitrate in regular crystals and of sp. gr. 4.75. Baryta is obtained from the hydrate in optically one- or two-axial crystals, of sp. gr. 5.32: but from the nitrate in regularly cubic crystals of sp. gr. 5.72. Magnesia is always obtained in the amorphous form of sp. gr. 3.42. Zinc oxide is obtained amorphous from the hydrate and carbonate of sp. gr. 3.47, but from the nitrate in hexagonal pyramids of sp. gr. 5.78.

Prof. Pritchett, of the Morrison Observatory, Glasgow, Mo., has made arrangements to drop a Time-Ball at Kansas City.

DETERMINATION OF SILICON IN IRON AND STEEL.—One grm. iron or steel is placed in a porcelain crucible with 25 c.c. nitric acid of 1.2 sp. gr. When the reaction is over 25 to 30 c.c. dilute sulphuric acid—1 part acid and 3 water are added, and the solution is heated till the nitric acid is entirely or nearly expelled. When the residue is sufficiently cool water is cautiously added, and the contents of the capsule are heated till the crystals are perfectly dissolved. The solution is then filtered as hot as possible, and the residue washed first with hot water, then with 25 to 30 c.c. hydrochloric acid of sp. gr. 1.20, and finally again with hot water. After drying and ignition the silica is obtained snow-white and granular.—T. M. BROWN.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

SATURDAY, MARCH 5, 1881.

MICROSCOPES AND THEIR OBJECTIVES.

WE are told by one maker of microscopes that he has orders in advance which will prevent his undertaking new work for at least four months from the present time. Supposing his statement to be true, and we heartily trust it is, it would appear to show that the number of those undertaking microscopical investigations is largely on the increase, and as the probabilities are that many of those now investing their money in microscopes and objectives, are doing so with little experience to guide them in their selection, it may be useful at this moment to take a review of the microscope market.

The purchase of the microscope stand and the objectives to use with it will be considered separately. They are usually purchased together, but there is no reason for doing so, and we would like to see each handled by a distinct branch of trade. To make a good microscope stand needs only the skill of a good worker in brass, under suitable direction. On the other hand, the manufacture of objectives, and the other optical parts of a microscope, requires the skilled labor of an optician.

In regard to the microscope stand, we would state that many improvements have been recently made, so that to avoid being saddled with one which may be considered obsolete, it would be as well to go directly to one who manufacturers his own stands, and direct him to make one to order; by so doing, the additional advantage will be secured of obtaining an instrument specially suited for particular work—a very important point.

The temptation is great to name one or two microscope stands which, in our opinion, are perfect in workmanship, designed on the best model and, withal, quite moderate in price; but to do so would court misinterpretation of our motives; so we may state that such firms as Bausch & Lomb, Beck, Bullock, Grunow, Schrauer, Slidel, Zentmayer, are all reliable American manufacturers, and that most of these firms now produce such an instrument as we would advise, at a cost of about 40 to 50 dollars for a Monocular stand, not including accessory apparatus or objectives. We have just seen an instrument, for the latter price, having perfection of workmanship and the latest improvements.

In regard to microscope objectives, the greatest caution should be employed by the inexperienced at this moment, for after twenty-five years experience in purchasing objectives, the present price-lists of opticians appear to us a perfect chaos of quotations.

In the first place, the objection has been raised by purchasers that object glasses of a certain focal length and stated aperture, vary in their linear magnifying power, among different makers, so that a quarter-inch which, for instance, should give 200 diameters with an A eye-piece, is found to be a 4–10, allowing only 120 diameters if purchased of another maker, or perhaps it will give 225 diameters similar to a 1–5th, when obtained from a third manufacturer—even when the conditions are alike. This, no doubt, originated in one of the tricks of the trade. A makes a 1–4th which, in resolving power, equals the 1-6th of B; in consequence, A claims at once a superiority of workmanship, and perhaps secures a reputation for objectives, when, if the truth was known, the 1-4th was in fact a 1-6th.

It must be remembered also that all objectives vary in quality even from the same maker, and that one may be given to an inexperienced person which is very far from the supposed standard of excellence; with some makers not more than one in twelve would be accepted by an expert.

Lastly, there appears to be a feeling that considerable improvements are imminent in the manufacture of objectives, rendering those of yesterday commercially valueless. If we may judge by a price list just forwarded, a panic appears to have commenced among those holding objectives made as recently as four years ago. By a circular, we are informed that the objectives of one of the most esteemed makers are now offered at prices 50 per cent. lower than those charged by the maker. "These lenses are of the *best quality* and *perfectly new*," "simply to close out our stock of these objectives." This offer is made by an optician in the same city with the original maker. Objectives which cost $150 can be had for $75, and others as follows: $110 for $55, $50 for $30. $40 for

$20, and one very noted objective for which the maker asks $60 is offered for $27.20.

We also notice the production of a 1–10th objective of 180° aperture, by a maker of reputation, which is sold at $25. A subscriber recently called at our office and stated that a 1-6th by the same maker, also sold at $25, divided the 19th band of Nobert's plate.

We mention these facts to show the variations in the present cost of microscope objectives, which must be perplexing to inexperienced purchasers. The regular price of a first-class 1–10th, of 180°, is about $85, and it would be interesting to compare the $25 article and note results; and it would also be useful to note how the cheaper glasses perform their work, as compared one with another.

As any expression of opinion on the merits of these objectives would be useless, without they were personally tested by us, we refrain from offering any advice on the subject. Microscope objectives are not struck in a die like medals, but are the result of manual operation, in which the individuality of the artist may be recognized and developed. In art the relative merits of the master are appreciated by the connoisseur, and a standard of value established; the same rule applies to optical instruments when perfection of work is aimed at. When Professor Asaph Hall discovered the satellites of Mars, it was necessary to have a telescope which would show an object six miles in diameter at a distance of 35,000,000 miles; when called upon to perform this feat, Clark's 32-inch objective responded in a manner which enabled Professor Hall to make one of the most important of recent astronomical discoveries. To appreciate this performance of the Washington telescope, we may state that it was equivalent to a person stationed at New York seeing an object at Boston which was two inches in diameter.

Such is the class of work we desire to find in microscopic objectives; probably there are only one or two men in this country able to produce it; but it is difficult to speculate as to what the future may bring forth.

WALKER PRIZES IN NATURAL HISTORY.

The Boston Society of Natural History offers a first frize of $60 to $100, and a second of $50, for the best memoirs, in English, on the following subjects: For 1881, The Evidences of the Extension of Tertiary Deposits seaward along the cost of Massachusetts; for 1882, The Occurrence, Microscopic Structure, and use of North American Fibre-plants (treating especially of the fibres employed by the native races); for 1883, Original Unpublished Investigations respecting the Life-History of any Animal. Prizes will not be awarded unless the papers are deemed of adequate merit.

THE ODONTORNITHES.

EXTINCT TOOTHED BIRDS OF NORTH AMERICA.

We merely desire in this place to acknowledge the receipt of the monograph, on the *Odontornithes*, an extinct order of toothed birds of North America, prepared by Professor O. C. Marsh, and published by order of the United States Government.

A review of this work is now in course of preparation by one well able to present Professor Marsh's discoveries in all their integrity, and we propose to publish the same with illustrations, which will convey to the readers of "SCIENCE" a fair estimate of the value of this work, which is considered by many to be one of the most important contributions to science, issued by the National Government at Washington.

Reserving our review of Professor Marsh's monograph for a future occasion, we now offer his own explanation regarding the work, as conveyed in a few introductory remarks:

"The remains of birds are among the rarest of fossils, and very few have been discovered except in the more recent formation. According to present evidence, the oldest known birds were imbedded in the Jurassic deposits of Europe, which have yielded three individuals belonging to the genus *Archæopteryx*, so well preserved that the more important characters can be determined. The only other remains of birds found in the Mesozoic of the Old World are a few specimens from the Cretaceous of England, which are too fragmentary to throw much light on the extinct forms they represent.

"The earliest traces of birds hitherto found in the strata of this country are from the Cretaceous, although we may confidently predict their discovery in the Jurassic beds, if not at a still lower horizon. There is at present no evidence whatever that any of the three-toed impressions in the Triassic, described as the foot prints of birds, were made by birds; and the proof now seems conclusive that nearly all of them are the tracks of Dinosaurian reptiles, bones of which occur in the same deposits.

"In the Cretaceous beds of the Atlantic coast, and especially in the green-sand region of New Jersey, various remains of birds have been found and described by the writer. These fossils, although often in excellent preservation, occur mainly as isolated bones, and hence their near affinities have not as yet been determined with certainty.

"Along the western slope of the Rocky Mountains, and especially on the adjoining plains in Kansas and Colorado, there is a series of Cretaceous strata remarkably rich in vertebrate fossils. The deposits are all marine, and, away from the mountains, they lie nearly horizontal. They have suffered much from erosion, and are still wasting away, especially along the river valleys. These beds consist mainly of a fine yellow chalk and calcareous shale, both admirably adapted to preserve delicate specimens, and here have been found the extinct birds which form the subject of the present memoir.

"The geological horizon of the known *Odontornithes* is in the Middle Cretaceous and corresponds to the strata named by the writer the "Pteranodon beds." The latter are included in sub-division number three, in Meek and Hayden's section. The accompanying fossils are Mosasauroid reptiles, which are very abundant; Plesiosaurs allied to Pliosaurus; Pterodactyles of the genus *Pteranodon;* and many fishes. With these occur Rudistes, and occasionally Ammonites, Belemnites, and various other Cretaceous invertebrates.

"The first bird fossil discovered in this region was the lower end of the tibia of *Hesperornis*, found by the writer in December, 1870, near the Smoky Hill River in Western Kansas. Specimens belonging to another genus of the *Odontornithes* were discovered on the same expedition. The extreme cold, and danger from hostile Indians, rendered a careful exploration at that time impossible.

"In June of the following year, the writer again visited the same region, with a larger party, and a stronger escort of United States troops, and was rewarded by the discovery of the skeleton which forms the type of *Hesperornis regalis*, Marsh. Various other remains of *Odontornithes* were secured, and have since been described by the writer. Although the fossils obtained during two months of explorations were important, the results of this trip did not equal our expectations, owing in part to the extreme heat (110° to 120° Fahrenheit, in the shade) which, causing sun stroke and fever, weakened and discouraged guides and explorers alike.

"A considerable part of these Cretaceous deposits still remain unexplored, and in the Autumn of 1872, a third expedition through this territory was undertaken by the writer with a small party. Additional specimens of much interest were secured, including the type of the genus *Apatornis*, and one nearly complete skeleton of *Hesperornis*—an ample reward for the hardship and danger we incurred.

"The specimens thus secured by these various expeditions have since been supplemented by important additions, collected in the same general region by different parties equipped and sent out by the writer, who no longer could give his personal supervision to work in that fiield. The fossil birds procured in this region, since 1870, by these different expeditions, include remains of more than one hundred different individuals of the *Odontornithes*. These are all in the Museum of Yale College, and form the material on which the present volume is based.

"A study of this extensive series of bird remains brings to light the existence, in this class, of two widely-separated types, which lived together during the Cretaceous period, in the same region, and yet differed more from each other than do any two recent birds. Both of these types possessed teeth, a character hitherto unknown in the class of birds, and hence they have been placed by the writer in a separate sub-class, the *Odontornithes*. One of these groups includes very large swimming birds, without wings and with the teeth in grooves (*Odontolcæ*), and is represented by the genus *Hesperornis*. The other contains small birds, endowed with great powers of flight, and having teeth in sockets (*Odontotormæ*), and biconcave vertebræ; a type best illustrated by the genus *Ichthyornis*. Other characters, scarcely less important, appear in each group, and we have thus a vivid picture of two primitive forms of bird structure, as unexpected as they are suggestive. A comparison of these two forms with each other, and with some recent birds, promises to clear away many difficulties in the genealogy of this class, now a closed type; and hence they are well worthy of the detailed description and full illustration here devoted to them.

"The fossil birds now known from the Cretaceous deposits of this country are included in nine genera and twenty species. These have all been described by the writer, and are represented, at present, by the remains of about one hundred and fifty different individuals. This is evidence of a rich and varied avian fauna in America during Mesozoic time, and likewise indicates what we may expect from future discoveries.

"The present volume is the first of a series of Monographs designed to make known to science the extinct vertebrate life of North America. In the investigation of this subject, the writer has spent the past ten years, much of it in the field, collecting, with no little hardship and danger, the material for study, and the rest in working out the characters and affinities of the ancient forms of life thus discovered.

"During this decade, the field work extending from the Missouri River to the Pacific Coast has so predominated as the subject unfolded, that a plan of gradual publication became a necessity. The more important discoveries were briefly announced soon after they were made, but only where the specimens on which they were based admitted of accurate determination. The principal characters of the new groups were next worked out systematically, and published with figures of the more important parts. When the investigation of a group is completed, the results, with full descriptions and illustrations, will be brought together in a monograph. This system has been carried out with the *Odontornithes*, and will be continued with the other groups. The investigation of several of these is now nearly completed, and the result will soon be ready for publication.

"The material is abundant for a series of monographs on the marvelous extinct vertebrates of this country, and the results already attained are full of promise for the future. A somewhat careful estimate makes the number of new species of extinct vertebrates, collected since 1868, and now in the Yale College Museum, about 1000. Nearly 300 of these have already been described by the writer, and some have been noticed or described by other authors, but at least one-half remain to be investigated.

"Among the new groups brought to light by these researches, and already made known by descriptions of their principal characters, are the following, which will be fully described in subsequent volumes of the present series.

"The first Pterodactyles or flying reptiles discovered in this country, were found by the writer in the same geological horizon with the *Odontornithes* described in the present memoir. These were of enormous size, some having a spread of wings of nearly twenty-five feet; but they were especially remarkable on account of having no teeth, and hence resembling recent birds. They form a new order, *Pteranodontia*, from the type genus *Pteranodon*. Of this group, remains of more than six hundred individuals are now in the Yale College Museum—ample material to illustrate every important point in their osteology.

"With these fossils were found also great numbers of Mosasauroid reptiles, a group which, although rare in Europe, attained an enormous development in this country, both in numbers and variety of forms. Remains of more than fourteen hundred individuals belonging to this order were secured during the explorations of the last ten years, and are now in the Museum of Yale College.

"The most interesting discoveries made in the Jurassic formation were the gigantic reptiles belonging to the new sub-order *Sauropoda*, including by far the largest land animals yet discovered. Another remarkable group of large reptiles found in the same formation were the *Stegosauria*. Other Dinosaurs from the same horizon, the 'Atlantosaurus beds,' show that this was the dominant form of vertebrate life in that age, and many hundred specimens of these reptiles are now in the Yale Museum. In a lower horizon of the same formation, the 'Sauranodon beds,' were found the remains of a peculiar new group of reptiles, the *Sauranodontia*, allied to *Ichthyosaurus*, but without teeth.

"In the Eocene deposits of the Rocky Mountains, the writer discovered a new order of huge mammals, the *Dinocerata*. Remains of several hundred individuals were secured, and a monograph on the group will follow the present memoir. In the same formation were found the remains of another new order of mammals, the *Tillodontia*, in many respects the most remarkable of any yet discovered. In the same Eocene deposits were secured the first remains of the fossil *Primates* known from North America as well as the first *Cheiroptera* and *Marsupialia*. Abundant material also was found in the same region to illustrate the genealogy of the Horse, and a memoir on this subject is in course of preparation.

CHOLESTEN.—This compound, $C_{26}H_{42}$, is a white amorphous powder, almost insoluble in alcohol, but soluble in ether. It resembles *c.* cholesterin in its physical and chemical properties.—W. E. Walitzky.

THE UNITY OF NATURE.

By the Duke of Argyll.

VI.

ON THE MORAL CHARACTER OF MAN, CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

The consciousness of unworthiness in respect to moral character is a fact as fundamental, and as universal in the human mind as the consciousness of limitation in respect to intellectual power. Both of them may exist in a form so rudimentary as to be hardly recognizable. The limits of our intelligence may be felt only in a dim sense of unsatisfied curiosity. The faultiness of our character may be recognized only in the vaguest emotions of occasional self-reproach. But as the knowledge of mankind extends, and as the cultivation of their moral faculties improves, both these great elements of consciousness become more and more prominent, and occupy a larger and larger place in the horizon of their thoughts. It is always the men who know most who feel most how limited their knowledge is. And so likewise it is always the loftiest spirits who are most conscious of the infirmities which beset them.

But although these two great facts in human consciousness are parallel facts, there is a profound difference between them; and to the nature and bearing of this difference very careful attention must be paid.

We have seen in regard to all living things what the relation is between the physical powers which they possess and the ability which they have to use them. It is a relation of close and perfect correspondence. Everything requisite to be done for the unfolding and upholding of their life they have impulses universally disposing them to do, and faculties fully enabling them to accomplish. We have seen that in the case of some animals this correspondence is already perfect from the infancy of the creature, and that even in the case of those which are born comparatively helpless, there is always given to them just so much of impulse and of power as is requisite for the attainment of their own maturity. It may be nothing more than the mere impulse and power of opening the mouth for food, as in the case of the chicks of many birds; or it may be the much more active impulse and the much more complicated power by which the young mammalia seek and secure their nourishment; or it may be such wonderful special instincts as that by which the newly hatched Cuckoo, although blind and otherwise helpless, is yet enabled to expel its rivals from the nest, and thus secure that undivided supply of food without which it could not survive. But whatever the impulse or the power may be, it is always just enough for the work which is to be done. We have seen, too, that the amount of prevision which is involved in those instinctive dispositions and actions of animals is often greatest in those which are low in the scale of life, so that the results for which they work, and which they do actually attain, must be completely out of sight to them. In the wonderful metamorphoses of insect life, the imperfect creature is guided with certainty to the choice and enjoyment of the conditions which are necessary to its own development; and when the time comes it selects the position, and constructs the cell, in which its mysterious transformations are accomplished.

All this is in conformity with an absolute and universal law in virtue of which there is established a perfect unity between these three things:—first, the physical powers and structure of all living creatures; secondly, those dispositions and instinctive appetites which are seated in that structure to impel and guide its powers; and thirdly, the external conditions in which the creature's life is passed, and in which its faculties find an appropriate field of exercise.

If Man has any place in the unity of Nature, this law must prevail with him. There must be the same correspondence between his powers and the instincts which incite and direct him in their use. Accordingly, it is in this law that we find the explanation and the meaning of his sense of ignorance. For without a sense of ignorance there could be no desire of knowledge, and without his desire of knowledge Man would not be Man. His whole place in Nature depends upon it. His curiosity, and his wonder, and his admiration, and his awe—these are all but the adjuncts and subsidiary allies of that supreme affection which incites him to inquire and know. Nor is this desire capable of being resolved into his tendency to seek for an increased command over the comforts and conveniences of life. It is wholly independent of that kind of value which consists in the physical utility of things. The application of knowledge comes after the acquisition of it, and is not the only, or even the most powerful, inducement to its pursuit. The real incitement is an innate appetite of the mind—conscious in various degrees of the mystery, and of the beauty, and of the majesty of the system in which it lives and moves; conscious, too, that its own relations to that system are but dimly seen and very imperfectly understood. In a former chapter we have seen that this appetite of knowledge is never satisfied, even by the highest and most successful exertion of those faculties which are, nevertheless, our only instruments of research. We have seen, too, what is the meaning and significance of that great Reserve of Power which must exist within us, seeing that it remains unexhausted and inexhaustible by the proudest successes of discovery. In this sense it is literally true that the eye is not satisfied with seeing, nor the ear filled with hearing. Every new advance has its new horizon. Every answered question brings into view another question unanswered, and perhaps unanswerable, lying close behind it. And so we come to see that this sense of ignorance is not only part of our nature, but one of its highest parts—necessary to its development, and indicative of those unknown and indefinite prospects of attainment which are at once the glory and the burden of humanity.

It is impossible to mistake, then, the place which is occupied among the unities of Nature by that sense of ignorance which is universal among men. It belongs to the number of those primary mental conditions which impel all living things to do that which it is their special work to do and in the doing of which the highest law of their being is fulfilled. In the case of the lower animals, this law, as to the part they have to play and the ends they have to serve in the economy of the world, is simple, definite, and always perfectly attained. No advance is with them possible, no capacity of improvement, no dormant or undeveloped powers leading up to wider and wider spheres of action. With Man, on the contrary, the law of his being is a law which demands progress, which endows him with faculties enabling him to make it, and fills him with aspirations which cause him to desire it. Among the lowest savages there is some curiosity and some sense of wonder, else even the rude inventions they have achieved would never have been made, and their degraded superstitions would not have kept their hold. Man's sense of ignorance is the greatest of his gifts, for it is the secret of his wish to know. The whole structure and the whole furniture of his mind is adapted to this condition. The highest law of his being is to advance in wisdom and knowledge: and his sense of the presence and of the power of things which he can only partially understand is an abiding witness of this law, and an abiding incentive to its fulfillment.

In all these aspects there is an absolute contrast between our sense of limitation in respect to intellectual power (or knowledge) and our sense of unworthiness in respect to moral character. It is not of ignorance, but of knowledge, that we are conscious here,—even the knowledge of the distinction between good and evil, and of that special sense which in our nature is associated with it, namely, the sense of moral obligation. Now it is a uni-

versal fact of consciousness as regards ourselves, and of observation in regard to others, that, knowing evil to be evil, men are nevertheless prone to do it, and that having this sense of moral obligation, they are nevertheless prone to disobey it. This fact is entirely independent of the particular standard by which men in different stages of society have judged certain things to be good and other things to be evil. It is entirely independent of the infinite variety of rules according to which they recognize the doing of particular acts, and the abstention from other acts, to be obligatory upon them. Under every variety of circumstance in regard to these rules, under every diversity of custom, of law, or of religion by which they are established, the general fact remains the same—that what men themselves recognize as duty they continually disobey, and what according to their own standard they acknowledge to be wrong they continually do.

There is unquestionably much difficulty in finding any place for this fact among the unities of Nature. It falls, therefore, in the way of this inquiry to investigate how this difficulty arises, and wherein it consists.

And here we at once encounter those old fundamental questions on the nature, the origin, and the authority of the Moral Sense which have exercised the human mind for more than two thousand years; and on which an eminent writer of our own time has said that no sensible progress has been made. This result may well suggest that the direction which inquiry has taken is a direction in which progress is impossible. If men will try to analyze something which is incapable of analysis, a perpetual consciousness of abortive effort will be their only and their inevitable reward.

For just as in the physical world there are bodies or substances which are (to us) elementary, so in the spiritual world there are perceptions, feelings, or emotions, which are equally elementary—that is to say, which resist all attempts to resolve them into a combination of other and similar affections of the mind. And of this kind is the idea, or the conception, or the sentiment of obligation. That which we mean when we say, "I ought," is a meaning which is incapable of reduction. It is a meaning which enters as an element into many other conceptions, and into the import of many other forms of expression, but it is itself uncompounded. All attempts to explain it do one or other of these two things—either they assume and include the idea of obligation in the very circumlocutions by which they profess to explain its origin; or else they build up a structure which, when completed, remains as destitute of the idea of obligation as the separate materials of which it is composed. In the one case, they first put in the gold, and then they think that by some alchemy they have made it; in the other case, they do not indeed first put in the gold, but neither in the end do they ever get it. No combinations of other things will give the idea of obligation, unless with and among these things there is some concealed or unconscious admission of itself. But in this, as in other cases with which we have already dealt, the ambiguities of language afford an easy means or an abundant source of self-deception. One common phrase is enough to serve the purpose—the "association of ideas." Under this vague and indefinite form of words all mental operations and all mental affections may be classed. Consequently those which are elementary may be included, without being expressly named. This is one way of putting in the gold and then of pretending to find it as a result. Take one of the simplest cases in which the idea of obligation arises, even in the rudest minds—namely, the case of gratitude to those who have done us good. Beyond all question, this simple form of the sense of obligation is one which involves the association of many ideas. It involves the idea of Self as a moral agent and the recipient of good. It involves the idea of other human beings as likewise moral agents, and as related to us by a common nature, as well as, perhaps, by still more special ties. It involves the idea of things good for them, and of our having power to confer these things upon them. All these ideas are "associated" in the sense of gratitude towards those who have conferred upon us any kind of favor. But the mere word "association" throws no light whatever upon the nature of the connection. "Association" means nothing but grouping or contiguity of any kind. It may be the grouping of mere accident—the associations of things which happen to lie together, but which have no other likeness, relation, or connection. But this, obviously, is not the kind of association which connects together the different ideas which are involved in the conception of gratitude to those who have done us good. What then is the associating tie? What is the link which binds them together, and constitutes the particular kind or principle of association? It is the sense of obligation. The associating or grouping power lies in this sense. It is the centre round which the other perceptions aggregate. It is the seat of that force which holds them together, which keeps them in a definite and fixed relation, and gives its mental character to the combination as a whole.

If we examine closely the language of those who have attempted to analyze the Moral Sense, or, in other words, the sense of obligation, we shall always detect the same fallacy—namely, the use of words so vague that under cover of them the idea of obligation is assumed as the explanation of itself. Sometimes this fallacy is so transparent in the very forms of expression which are used, that we wonder how men of even ordinary intelligence, far more men of the highest intellectual power, can have failed to see and feel the confusion of their thoughts. Thus, for example, we find Mr. Grote expressing himself as follows: "This idea of the judgment of others upon our conduct and feeling as agents, or the idea of our own judgment as spectators in concurrence with others upon our own conduct as agents, is the main basis of what is properly called Ethical sentiment."[1] In this passage the word "judgment" can only mean moral judgment, which is an exercise of the Moral Sense; and this exercise is gravely represented as the "basis" of itself.

Two things, however, ought to be carefully considered and remembered in respect to this elementary character of the Moral Sense. The first is, that we must clearly define to ourselves what the idea is of which, and of which alone, we can affirm that it is elementary; and secondly, that we must define ourselves as clearly, if it be possible to do so, in what sense it is that any faculty whatever of the mind can really be contemplated as separable from, or as uncombined with, others.

As regards the first of these two things to be defined, namely, the idea which we affirm to be simple or elementary, it must be clearly understood that this elementary character, this incapability of being reduced by analysis, belongs to the bare sense or feeling of obligation, and not at all, or not generally, to the processes of thought by which that feeling may be guided in its exercise. The distinction is immense and obvious. The sense of rightness and of wrongness is one thing; the way in which we come to attach the idea of right or wrong to the doing of certain acts, or to the abstention from certain other acts, is another and a very different thing. This is a distinction which applies equally to many other simple or elementary affections of the mind. The liking or disliking of certain tastes or affections of the palate is universal and elementary. But the particular tastes which are the objects of liking or of aversion are for the most part determined by habits and education. There may be tastes which all men are so coustituted as necessarily to feel disgusting; and in like manner there may be certain acts which all men everywhere must feel to be con-

[1] "Fragments on Ethical Subjects," pp. 9, 10.

trary to their sense of obligation. Indeed we shall see good reason to believe that this not only may bé so, but must be so. But this is a separate subject of inquiry. The distinction in principle is manifest between the sense itself and the laws by which its particular applications are determined.

The second of the two things to be defined—namely, the sense in which any faculty whatever of the mind can really be regarded singly, or as uncombined with others —is a matter so important that we must stop to consider it with greater care.

The analogy is not complete, but only partial, between the analysis of Mind and the analysis of Matter. In the analysis of Matter we reach elements which can be wholly separated from each other, so that each of them can exist and can be handled by itself. In the analysis of Mind we are dealing with one organic whole; and the operation by which we break it up into separate faculties or powers is an operation purely ideal, since there is not one of these faculties which can exist alone, or which can exert its special functions without the help of others. When we speak, therefore, of a Moral Sense or of Conscience, we do not speak of it as a separate entity any more than when we speak of Reason or of Imagination. Strictly speaking, no faculty of the mind is elementary in the same sense in which the elements of Matter are (supposed to be) absolutely simple or uncombined, Perhaps there is no faculty of the mind which presents itself so distinctly and is so easily separable from others as the faculty of Memory. And yet Memory cannot always reproduce its treasures without an effort of the Will, nor, sometimes , without many artificicial expedients of Reason to help it in retracing the old familiar lines. Neither is there any faculty more absolutely necessary than Memory to the to the working of every other. Without Memory there could not be any Reason, nor any Reflection nor any Conscience. In this respect all the higher faculties of the human mind are much more inseparably blended and united in their operation than those lower faculties which are connected with bodily sensation. These lower faculties are indeed also parts of one whole, are connected with a common centre, and can all be paralyzed when that centre is affected. But in their ordinary activities their spheres of action seem widely different, and each of them can be, and often is, seen in apparently solitary and independent action. Sight and taste and touch and hearing are very different from each other—so separate indeed that the language of the one can hardly be translated into the language of the other. But when from these lower faculties, which are connected with separate and visible organs of the body, and which we possess in common with the brutes, we ascend to the great central group of higher and more spiritual faculties which are peculiar to Man, we soon find that their unity is more absolute, and their interdependence more visibly complete. Ideally we can distinguish them, and we can range them in an ascending order. We can separate between different elements and different processes of thought and in accordance with these distinctions we can assign to each of them a separate faculty of the mind. We think of these separate faculties as being each specially apprehensive of one kind of idea, or specially conducting one kind of operation. Thus the reasoning faculty works out the process of logical sequence, and apprehends one truth as the necessary consequence of another. Thus the faculty of Reflection passes in review the previous apprehensions of the Intellect, or the fleeting suggestions of Memory and of Desire, looks at them in different aspects, and submits them now to the tests of reasoning, and now to the appreciations of the Moral Sense. Thus, again, the supreme faculty of Will determines the subject of investigation, or the direction of thought, or the course of conduct. But although all these faculties may be, and indeed must sometimes be, conceived and regarded as separate, they all more or less involve each other; and in the great hierarchy of powers, the highest and noblest seem always to be built upon the foundations of those which stand below. Memory is the indispensable servant of them all. Reflection is ever turning the mind inward on itself. The logical faculty is ever rushing to its own conclusions as necessary consequences of the elementary axioms from which it starts,and which are to it the objects of direct and intuitive apprehension. The Moral Sense is ever passing its judgments upon the conduct of others and of ourselves; whilst the Will is ever present to set each and all to their proper work. And the proper work of every faculty is to see some special kind of relation or some special quality in things which other faculties have not been formed to see. But although these qualities in things are in themselves separate and distinct, it does not at all follow that the separate organs of the mind, by which they are severally apprehended, can ever work without each other's help. The sense of logical necessity is clearly different from the sense of moral obligation. But yet as Reason cannot work without the help of Memory, so neither can the Moral Sense work without the help of Reason. And the elements which Reason has to work on in presenting different actions to the judgment of the Moral Sense may be, and often are, of very great variety. It is these elements, many and various in their character, and contributed through the help and concurrence of many different faculties of the mind that men are really distinguishing and dissecting when they think they are analyzing the Moral Sense itself. What they do analyze with more or less success is not the Moral Sense, but the conditions under which that Sense comes to attach its special judgments of approval or of condemnation to particular acts or to particular motives.

And this analysis of the conditions under which the Moral Sense performs its work, although it is not the kind of analysis which it often pretends to be, is nevertheless in the highest degree important, for although the sense of obligation, or, as it is usually called, the Moral Sense, may be in itself simple, elementary, and incapable of reduction, it is quite possible to reach conclusions of the most vital interest concerning its nature and its functions by examining the circumstances which do actually determine its exercise, especially those circumstances which are necessary and universal facts in the experience of mankind.

There is, in the first place, one question respecting the Moral Sense which meets us at the threshold of every inquiry respecting it, and to which a clear and definite answer can be given. This question is—What is the subject-matter of the Moral Sense? or, in other worda, what is the kind of thing of which alone it takes any cognizance, and in which alone it recognizes the qualities of right and wrong?

To this fundamental question one answer, and one answer only can be given. The things, and the only things of which the Moral Sense takes cognizance are the actions of men. It can take no cognizance of the actions of machines, nor of the actions of the inanimate forces of Nature, nor of the actions of beasts, except in so far as a few of these may be supposed to possess in a low and elementary degree some of the characteristic powers of Man. Human conduct is the only subject-matter in respect of which the perceptions of the Moral Sense arise. They are perceptions of the mind which have no relation to anything whatever except to the activities of another mind constituted like itself. For, as no moral judgment can be formed, and no moral perception can be felt, except by a moral agent, so neither can it be formed in respect to the conduct of any other agent which has not, or is assumed not to have a nature like our own—moral, rational and free.

And this last condition of freedom, which is an essential one to the very idea of an agency having any moral character, will carry us a long way on toward a farther definition of the subject-matter on which the Moral Sense is exercised. It is as we have seen, human conduct. But it

is not human conduct in its mere outward manifestations, for the only moral element in human conduct is its actuating motive. If any human action is determined not by any motive whatever, but simply by external or physical compulsion, then no moral element is present at all, and no perception of the Moral Sense can arise respecting it. Freedom, therefore, in the sense of exemption from such compulsion, must be assumed as a condition of human action absolutely essential to its possessing any moral character whatever. There can be no moral character in any action, so far as the individual actor is concerned, apart from the meaning and intention of the actor. The very same deed may be good, or, on the contrary devilishly bad, according to the inspiring motive of him who does it. The giving of a cup of cold water to assuage suffering, and the giving it to prolong life in order that greater suffering may be endured, are the same outward deeds, but are exactly opposite in moral character. In like manner, the killing of a man in battle and the killing of a man for robbery or revenge, are the same actions; but the one may be often right, whilst the other must be always wrong, because of the different motives which incite the deed. Illustrations of the same general truth might be given as infinite in variety as the varying circumstances and conditions of human conduct. It is a truth perfectly consistent with the doctrine of an Independent Morality, Every action of a voluntary agent has, and must have, its own moral character, and yet this character may be separate and apart from its relation to the responsibility of the individual man who does it. That is to say, every act must be either permitted, or forbidden, or enjoined, by legitimate authority, although the man who does it may be ignorant of the authority or of its commands. And the same proposition holds good if we look upon the ultimate standard of morality from the Utilitarian point of view. Every act must have its own relation to the future. Every act must be either innocent, or beneficent, or hurtful in its ultimate tendencies and results. Or, if we like to put it in another form, every act must be according to the harmony of Nature or at variance with that harmony, and therefore an element of disorder and disturbance. In all these senses, therefore, we speak, and we are right in speaking of actions as in themselves good or bad, because we so speak of them according to our own knowledge of the relation in which they stand to those great standards of morality, which are fact and not mere assumptions or even mere beliefs. But we are quite able to separate this judgment of the act from the judgment which can justly be applied to the individual agent. As regards him, the act is right or wrong, not according to our knowledge, but according to his own. And this great distinction is universally recognized in the language and (however unconsciously) in the thoughts of men. It is sanctioned, moreover, by Supreme Authority. The most solemn prayer ever uttered upon earth was a prayer for the forgiveness of an act of the most enormous wickedness, and the ground of the petition was specially declared to be that those who committed it "knew not what they did." The same principle which avails to diminish blame, avails also to diminish or extinguish merit. We may justly say of many actions that they are good in themselves, assuming, as we naturally do, that those who do such actions do them under the influence of the appropriate motive. But if this assumption fails in any particular case, we cannot and we do not, credit the actor with the goodness of his deed. If he has done a thing which in itself is good in order to compass an evil end, then, so far as he is concerned, the deed is not good, but bad, It may indeed be worse in moral character than many other kinds of evil deeds, and this just because of the goodness usually attaching to it. For this goodness may very probably involve the double guilt of some special treachery, or some special hypocrisy; and both treachery and hypocrisy are in the highest degree immoral. It is clear that no action, however apparently benevolent, if done from some selfish or cruel motive, can be a good or a moral action.

It may seem, however, as if the converse of this proposition cannot be laid down as broadly and as decidedly. There are deeds of cruelty in abundance which have been done, ostensibly at least, and sometimes, perhaps, really from motives comparatively good, and yet from which an enlightened Moral Sense can never detach the character of wickedness and wrong. These may seem to be cases in which the motive does not determine the moral character of the action, and in which our Moral Sense persists in condemning the thing done in spite of the motive. But if we examine closely the grounds on which we pass judgment in such cases, we hall not, I think, find them exceptions to the rule or law that the purpose or intention of a free and voluntary agent is the only thing in which any moral goodness can exist, or to which any moral judgment can be applied. In the first place, we may justly think that the actors in such deeds are to a large extent themselves responsible for the failure in knowledge, and for the defective Moral Sense which blinds them to the evil of their conduct, and which leads them to a wrong application of some motive which may in itself be good. And in the second place, we may have a just misgiving as to the singleness and purity of the alleged purpose which is good. We know that the motives of men are so various and so mixed, that they are not always themselves conscious of that motive which really prevails, and we may have often good reasons for our convictions that bad motives unavowed have really determined conduct for which good motives only have been alleged. Thus, in the case of religious persecution, we may be sure that the lust of power and the passion of resentment against those who resist its ungovernable desires, have very often been the impelling motive, where nothing but the love of truth has been acknowledged. And this at least may be said, that in the universal judgment of mankind, actions which they regard as wrong have not the whole of that wrongfulness charged against the doers of them, in proportion as we really believe the agents to have been guided purely and honestly by their own sense of moral obligation.

On the whole, then, we can determine or define with great clearness and precision the field within which the Moral Sense can alone find the possibilities of exercise—and that field is the conduct of men;—by which is meant not their actions only, but the purpose, motive, or intention by which the doing of these actions is determined. This conclusion, resting on the firm ground of observation and experience, is truthfully expressed in the well-known lines of Burns:—

> "The heart's aye the part aye
> Which makes us right or wrang."

And now it is possible to approach more closely to the great central question of all ethical inquiry:—Are there any motives which all men under all circumstances recognize as good? Are there any other motives which, on the contrary, all men under all circumstances recognize as evil? Are there any fundamental perceptions of the Moral Sense upon which the standard of right and wrong is planted at the first, and round which it gathers to itself, by the help of every faculty through which the mind can work, higher and higher conceptions of the course of duty?

(To be continued.)

Physiological Effects of Glycerin.—Chemically pure glycerine if injected under the skin of dogs proves fatal within twenty-four hours if the dose reaches 8 to 10 grms. per kilo. of the weight of the animal. The symptoms are comparable to those of acute alcoholism.—M M. Beaumetz and Audigé.

ATMOSPHERIC OZONE FOR JANUARY, 1881.

By L. P. Gratacap.

The memorable discovery of Ozone by Schönbein, in 1840, bequeathed to the scientific world one of its questiones vexatæ, about which opinions and experiments seem to have been equally at variance. As regards its constitution and essential nature there seems little reason to doubt it is a condensed form of oxygen, according to the views of Andrews and Tait, and that it displays the characteristic properties of that gas in an intensified degree. Its existence in the air can be hardly less questioned, but the extent and origin of its presence are involved in obscurity, and partly from the modifying influence of local circumstances and the identity of its reactions with other atmospheric bodies the conclusions of various experimenters are either equivocal or contradictory. The fact that chlorine, sulphurous fumes, the nitrogen oxides, affect the test papers in the same manner as ozone, and that humidity of the atmosphere, strong winds, bright sunshine, or local nuisances exaggerate or diminish the normal reaction, renders it difficult to eliminate the error introduced by their adventitious influence. The results here given were obtained with test papers of starch and iodide of calcium, prepared, presumably, like those of Dr. Moffat, from starch and iodide of potassium, and compared, after the test, with a scale of colors similar to Negretti and Zambra's.

After E. Schöne's recent condemnation of ozone tests made in this way, they may appear valueless, but it would hardly seem, admitting the justice of Schöne's strictures, that their comparative showing would be seriously impaired. The coloration obtained was in a great measure due to ozone, and its increase or decrease was due in the same proportion to an increase or decrease of this re-agent; the contemporaneous influence of nitrogen oxides may have deepened the tints, it certainly could not have neutralized them, and inasmuch as the papers were kept moist the effects of the varying humidity of the air were, in a measure, cancelled. Precautions against the disturbing influence of winds and that of strong sunshine were also taken. Duplicate observations were taken at 10 feet and at 40 feet from the ground, and their average (though in nearly all cases they proved identical one with the others) recorded, as the color-mark of the hours they were exposed.

Observations were taken every 12 hours, dividing the 24 between day and night, and notes kept of the weather. As a rule, the papers exposed at an elevation were more deeply colored than those near the ground, though this was probably due to a freer circulation of air. The papers at the periods of strongest ozonization were changed throughout; at other times they were marked in spots and near the edges, showing an unequal sensitiveness to the re-agents. In supplementary trials on the effect of the wind, it was found that those papers exposed to the wind were sometimes one-third deeper in tint than the protected ones, and reached their maximum much quicker. These contrasts were, of course, lessened with a diminished velocity of wind.

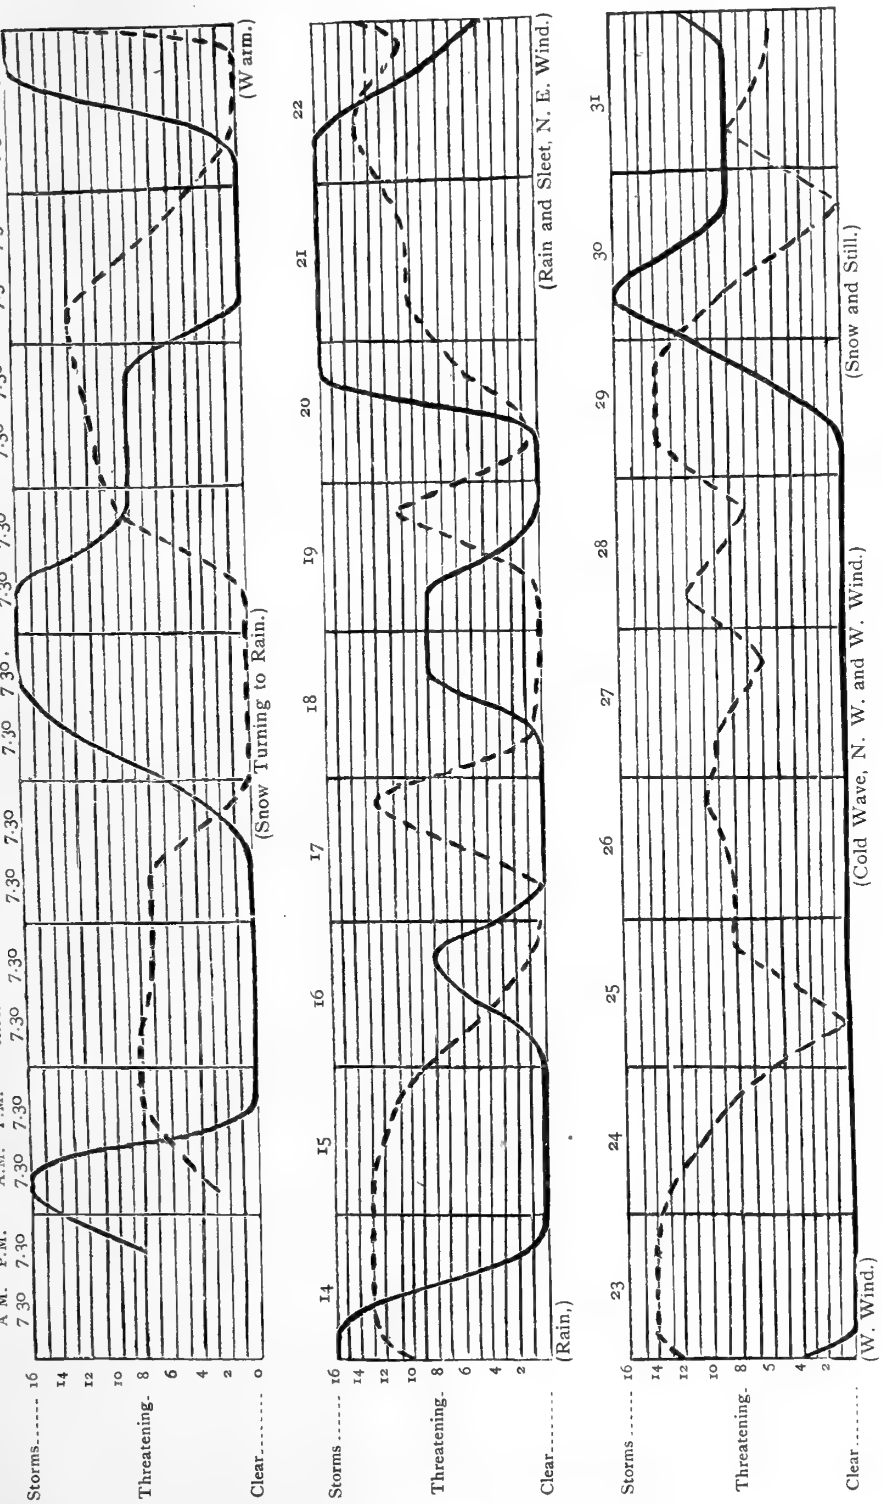
The manifestations of ozone followed, as a rule, lowered barometric pressure and rising temperature, in other words, they were coincident with change of weather. This is an interesting confirmation of Houzeau's experiments, and in the attempt I make below to give this a graphic demonstration this generalization appears, *i. e.*, that a wave of ozonization follows the storm wave, lagging somewhat behind it, and appreciably corresponding in duration and intensity to the force and continuance of the air wave which preceded it.* In this connection it will be noticed that threatening weather on the 16th and 18th was followed by a sudden projection of the ozone curve which as rapidly subsides, indicating either atmospheric disturbances responsive to an incipient but unfinished change of weather, or else undulations of ozonization coming from some neighboring storm centre or both. Further on the curve of ozonization rises somewhat before that of the weather, and I apprehend this may often or always happen when storms of unusual severity and violence are about to traverse a district. The thrill of ozonization recorded on the papers taken in on the morning of the 20th were prophetic of the fierce and extraordinary tempest which devastated New York and its vicinity upon the 21st.

The high readings from the 25th to 29th accompanied the advent of a cold wave in the Hudson River Valley on the night of the 24th, which sent the mercury down to 15° below 0° at Poughkeepsie and brought colder weather to New York and its vicinity, lasting four days, with strong N.-W. and W. winds. This appears analogous to the strong ozonization concurrent with storms, etc.; the atmospheric disturbance originating the cold wave propagated an ozone wave which appears simultaneously with the former. It is not probably due simply to an apparent increase of normal ozone from the rapid passage of air currents past the tester. This latter effect is doubtless efficient in heightening the entire result, but the wind appears to act as an ozone carrier, bringing into one area supplies of this gas formed in a different and removed one. Indeed it does not appear unwise to speculate upon the possibility of the wind acting as an ozone generator since the irruption of a volume of air at a high velocity of different temperature and density from that of the points over which its path sweeps, must comprise electrical changes, discharges and perturbations. Such effects would correspond in their intensity with the violence and character of the air blast, and we might find the neighboring areas to the track of a cyclone strongly ozonized. As a matter of observation the strong ozonization on the 29th succeeded the strong winds which ushered in the cold of the 27th and 28th. And in any case the deeper tints during wind indicate justly enough the increased prevalence of ozone in the areas swept over by the gale. That wind is not always efficient in changing the ozone papers was shown in Daremberg's experience at Mentone, where, although variations were caused by the wind, in some instances along the sea board the coloration did not at all respond to the strength of the former, and Houzeau is of the opinion that dry winds have slight influence upon the papers.

The cold wave was followed on the 30th by a still snow storm, the shower of pellets falling through an atmosphere unmoved by even a current of air. Threatening weather succeeded the cessation of the snowfall only to usher in the fierce storm of February 1st, when snow, wind, and a low temperature united to arrest life and motion upon the thoroughfares of land and water. The ozone curve responds but feebly to these meterological perturbations until February 1st, when it slowly rises, recalling Houzeau's conjectures as to storms which generated ozone and storms which did not.

It may seem superfluous, if not trivial, to record any observations upon atmospheric ozone when the whole subject is involved in a fog of scientific confusion, contempt and obloquy. It may be said that these observations presented no inconsistent, aberrant or contradictory results, and that to the general student of our local metereology they may in this graphic form exhibit some features of interest. The chart is simply suggestive and absolutely artificial; the numbers on the left of the lines indicate degrees of coloration and the weather line is determined by three points: clear, threatening and stormy. The readings were made at West Brighton, Staten Island, in New York Harbor, the maxima of colorations, and hence ozone, considered as coincident with the time at which the reading was taken, 7.30, night and morning, which must be at times barely approximative.

* As regards the sensible effects of the ozone following by many hours the opening of the storm on the 9th and 13th, the reactions appeared concurrently with a change in the weather from snow to rain. On the other hand, the storm of the 21st opened with rain.



OZONE AND WEATHER CURVE, JANUARY, 1881, STATEN ISLAND, N. Y.

——— WEATHER CURVE. - - - - - OZONE CURVE.

NOTE ON THE "POSTERIOR BRAIN" OF STEGOSAURUS.

In a paper before the National Academy of Sciences in November last, and more recently in an illustrated article in the *American Journal of Science*, February, 1881, Professor O. C. Marsh has described certain remarkable peculiarities of *Stegosaurus ungulatus,* one of the Dinosaurian Reptiles of the American Jurassic formation.

Judging from the figures, which are said to be reduced to one-sixteenth of the natural size, the arm of this species must have been about one meter in length, while the leg was about twice as long. "The great disproportion in size between the fore and hind limbs, as well as the structure of the principal joints in each, show plainly that *Stegosaurus* walked mainly as a biped. The massive posterior limbs, and the huge tail doubtless formed a tripod on which the animal rested at times, while the fore limbs were used for prehension or defense. The heavy dermal plates and powerful spines probably rendered the latter an easy task."

After recalling the statement which had been made by him in a previous article, that, proportionately, "this reptile had the smallest brain of any known land vertebrate," Professor Marsh describes with some detail "a very large chamber in the sacrum, formed by an enlargement of the spinal canal. This chamber was ovate in form, and strongly resembled the brain case in the skull, although very much larger, being at least ten times its size. . . . A perceptible swelling in the spinal cord of various recent animals has been observed in the pectoral and pelvic regions, where the nerves are given off for the anterior and posterior limbs; and in extinct forms some very noticeable cases are recorded, especially in Dinosaurs. . . . In some allied forms, *Camptonotus* for example, where the disproportion between the fore and hind limbs is nearly as marked, the sacral enlargement of the spinal cord is not one-fourth as great as in *Stegosaurus.* It is an interesting fact that in young individuals of *Stegosaurus* the sacral cavity is proportionately larger than in adults, which corresponds to a well-known law of brain growth. The physiological effects of a posterior nervous centre, so many times larger than the brain itself is a suggestive subject, which need not be here discussed. It is evident, however, that in an animal so endowed, the posterior part was dominant."

In the hope that Professor Marsh may continue his important observations and reflections upon this subject, attention is called to the following points:

1. It seems to be taken for granted that "the posterior nervous centre" was as large as the sacral cavity. This is hardly warranted, although it is certainly favored by the size of the sacral foramina. The cranial part of the elephant's skull is far larger than is required for the lodgment of its brain, on account of the surface needed for the attachment of the immense cervical muscles. With many fishes, especially some skates and the *Lophius,* the brain occupies but a small part of the capacious cranial cavity. May it not be, then, that the sacral cavity of *Stegosaurus* was enlarged, in part at least, in correlation with a general enlargement of the whole pelvis, in reference to the functions of the legs?

2. Unless such examinations have been made already, it would be well to ascertain the condition of the myelon in the kangaroos, and that of the sacral cavity in *Diprotodon* and *Megatherium,* all of which may be compared with *Stegosaurus* in respect to the size of the legs, or their employment in connection with a large tail.

It would be interesting to know the form and size of the entire myelonal canal of *Stegosaurus.* The paper leaves us in doubt as to whether the writer considers the "posterior nervous centre" as the homologue of the ordinary "lumbar enlargement" of the myelon in man and other vertebrates. If not, may it be the not yet wholly abbreviated representative of what the late Prof. Jeffries Wyman referred to in his paper "On Symmetry and Homology in Limbs"? In some adult fishes the spinal marrow ends in a ganglionic enlargement forming a kind of caudal brain. We have found such a ganglion quite conspicuous in the American *Lophius.*" In either case, it is probable that the remarkable condition of things in *Stegosaurus,* as described by Prof. Marsh, would have appeared to Prof. Wyman as an example of the law of organic polarity in the form of "fore-and hind symmetry," which has been advocated by him, by Dr. Coues, and by the writer of the present notice.

B. G. W.

THE ROMANCE OF ASTRONOMY.—Those interested in astronomy will be pleased to know that Professor R. Kalley Miller's delightful work "The Romance of Astronomy," has been published by the "Humbolt Library." Professor Miller is a professor at Cambridge, England, and has received aid from his distinguished colleagues, Sir William Thomson and Professor Tait. An appendix by Mr. R. A. Proctor is added. We remind our readers that the above work can be purchased for 15 cents, and that under the advantages now offered by club rates (to subscribers only), the 24 numbers issued annually can be secured for $2.25—an average of about 9 cents each.

ATMOSPHERIC DUST.

AT the period of the great debate on spontaneous generation between M. Pasteur and Pouchet, the latter was the first to draw attention to the fact, that some of the minute spherical granulations, discovered by the microscope in dust deposited from the air in various regions of the globe, were essentially composed of silica. That they had often been mistaken for eggs of infusoria or for micrococci was very evident; but when the dust was submitted to complete calcination in a platinum crucible the same grains were still visible, with the same forms and dimensions as before.

I have more than once repeated this experiment of Pouchet's, but I have also made the opposite one and examined the action of heat upon micrococci, diatoms and oscillariæ, which are supposed to contain large quantities of silica.

There is no doubt that the dust of the atmosphere reveals to the microscope, besides the larger mineral fragments mostly of an angular shape, exceedingly minute circular or spherical bodies, being often not more than 0.001 of a millimetre in diameter, and very similar in size and shape, which resist the action of a white heat in contact with the air, and that of strong hydrochloric acid. In some of my observations they were remarkably numerous. Both before and after the action of heat they are more or less transparent. What can be the origin of these singular objects?

The same experiments repeated with siliceous algæ, such as those belonging to the large family of the *diatomaceæ,* and with the *micrococci* of impure waters or vegetable infusions, showed me that they do not retain their forms after being subjected to the above treatment, and that in many instances they can be totally destroyed by heat on the object glass itself. On the other hand, the fossil diatoms resisted the action of heat and acids and retained their forms. I can draw only one conclusion from these observations: namely, that the minute siliceous bodies found in the atmosphere are also fossil—they are micrococci of another age.—Dr. T. L. PHIPSON, F.C.S.

SILVER BROMIDE.—The action of light upon this substance varies according as the bromide is in the state of emulsion in an indifferent medium, like collodian, or in an organic substance readily oxidisable, like gelatine. Temperature, moisture, and mechanical pressure do not appear to have any influence.

ASTRONOMICAL MEMORANDA.

THE CORDOBA OBSERVATORY.

In the fall of 1870, Dr. B. A. Gould, formerly director of the Dudley Observatory, Albany, arrived in Cordoba, for the purpose of establishing a National Argentine Observatory, and making the requisite observations for forming a complete catalogue of the principal fixed stars of the southern hemisphere. A long delay of about two years, in the receipt of the instrument necessary to make these observations, has been the cause of giving to the world the *Uranometria Argentina*, a work analagous to the Uranometry of Argelander, which rendered such signal service to astronomy more than forty years ago.

Cordoba is situated about five hundred miles northwest of Buenos Ayres, the Observatory occupying a height upon the outskirts of the town, in latitude 31° 25′ 15.″4 south ; longtitude oh., 51m., 27s., east from Washington. The equipment of the Observatory consists of a 12.5 inch equatorial (object glass by Fitz) used mainly for observing comets, etc.; a smaller equatorial of about 8 inches aperture, devoted to observations of variable stars ; a Zöllner photometer ; and various accessory instruments. But the most important instrument is a Repsolds' Meridian Circle of about 8 inches aperture, which was mounted and ready for use in September, 1872. With this instrument observations of zones from 23° south, to 80° south declination—760 zones embracing 106,000 observations—have been completed, and the reductions have been well advanced. To determine absolute positions of all stars included in this catalogue, the instrumental constants were determined before and after each zone by a series of observations "consisting of transits of two standard time stars, as well as of one circumpolar star above, and one below the pole, together with measurements of nadir, collimation and level."

Dr. Gould has established, though necessarily on a limited scale, a Signal Service which will doubtless develop rapidly, when meteorology receives more attention in South America than it does at present. Meanwhile data of inestimable value are being collected at very slight expense, by interesting many of the intelligent land owners, in making sucn observations of the barometer, thermometer, etc., as may be made with little outlay of time and trouble. A Time Signal is sent at noon once a week, over the available telegraph lines of the country.

A force of four observers and several copyists, mostly Americans, is engaged upon the work in the various departments, and Dr. Gould has taken with him, within the past few months, a photographer, in order to obtain exact representations of several very interesting star clusters, which can be compared directly with the appearance of the cluster at any future time, and thus afford a means of detecting any changes which may occur in the relative positions of the component stars.

It is to be hoped that the political party now in power, —under whose auspices these institutions have originated and have been maintained—will retain its influence in the government, and thus be enabled to promote the interests of science in the country.

DISCOVERY OF A NEW ASTEROID.

The Smithsonian Institution has received from Professor Foerster, of Berlin, the announcement of the discovery, by Palisa, of a planet of the tenth magnitude, in eleven hours thirty-nine minutes Right Ascension, eight degrees twenty-five minutes north declination, with a daily motion of one minute, north. This discovery brings the total number of asteroids up to two hundred and twenty, making the eighth discovered since February 6, 1880. The date of discovery is omitted.

IN a paper recently read before the Royal Astronomical Society, Mr. Stone has called attention to "some difficulties connected with the determination of the diameter of Mars." Upon examining the Greenwich observations of the diameter, since 1851, very marked personal equations have been noticed in the different observers, discrepancies which seem somewhat difficult to account for. Mr. Stone says, "it looks as if there were two different diameters of Mars observed,—one when Mars is comparatively near to us, and the other when it is at its greatest distance from us. The result is that as far as one can trace it, there is a distinct break of continuity between the smaller and the larger measures ; as if the observers had included the planet's atmosphere when Mars is distant."

SWEDEN has decided to take part in the international meteorological and magnetic observations in the Polar regions, and will establish two observatories, one at Masselbay in Spitzbergen, and one at Haparanda at the head of the Gulf of Boothia. Haparanda is to be well supplied with self-registering and printing meteorological apparatus, and with astronomical instruments to carry on a series of regular observations.

PROFESSOR PICKERING has called attention to the peculiar resemblance between the spectrum of the star Oeltzen 17681 and that of the three stars discovered by Wolf and Rayet in 1867, (*Comptes Rendus*, vol. lxv., p. 292). The relative brightness is found to be different in these spectra, and the subject promises to repay further investigation. W.C.W.

Washington, D. C , March 3, 1881.

THE DAVIDSON ASTRONOMICAL OBSERVATORY AT SAN FRANCISCO, CALIFORNIA.

Prof. George Davidson, of the United States Coast and Geodetic Survey, has established a private observatory in San Francisco, and mounted the six-and-a-half inch Equatorial which was exhibited at the Centennial, but which has now a Villarcean governor, spectrescope, and other improvements.

The geographical position of this observatory is :
Latitude = 37° 47′ 22″.3 north.
Longitude = 122° 24′ 39″.0 west of Greenwich.
In time = 8^h 09^m $3^s.60$ west of Greenwich.
This fixes it as the most western observatory in America.

To observe the total solar eclipse of January 11, 1880, Prof. Davidson transported the instrument and the observatory to the summit of Santa Lucia Mountain, about thirty-five miles southward of Monterey, and six thousand feet elevation above the Pacific ocean. In this undertaking everything had to be carried up four thousand feet over a very steep and rugged trail by pack mules ; and the party encountered one of the fiercest snow stor msof that coast, but successfully accomplished the object of the undertaking which was made under the directions of the Superintendent of the Coast Survey. Whenever opportunities offer for observing at not less than ten thousand feet elevation, he will transport it to these high stations. [It was intended to use it in 1879 at two of the coast survey stations occupied in the Sierra Nevada having elevations of 9800 to 10,600 feet, but unfortunately it was not received in season.]

Mr. Davidson has been engaged in regular coast survey duties upon the Pacific almost continuously since the Spring of 1850, and has had large experience in observing at great elevations.

AN international exhibition connected with electricity will open in Paris, August 1, 1881, and will close on the 15th of November following.

SCIENCE IN FRANCE.

PARIS, February 12, 1881.

There is so much at present which is both novel and important in the scientific world, that I fear, in my endeavors to do full justice to everything, I shall, by attempting too much, find myself in a position analogous with that of a certain unfortunate person mentioned in history, who, while striving to seat himself upon two chairs simultaneously, fell ignominiously to the ground.

But let us not waste time in odious comparisons! The news has probably long since reached you of a wonderful fossil forest which has recently been discovered in Hindoostan, and of a prehistoric grotto somewhere on the border line of France, containing various kinds of warlike weapons of an exceedingly primitive design, together with a single human tooth. It is not of these, however, that I intend to speak, as beyond the facts themselves nothing of particular interest remains to be told.

In the medical world a little instrument newly invented, is attracting considerable attention. It is called the *crayon feu* and is worthy of something more than a passing description.

That all intelligent physicians recommend instant cauterization when a person has been bitten by a mad dog, or indeed a dog of any sort, is a well-known fact. It is not, however, generally speaking, an easy matter to find an appropriate piece of iron and a lighted fire all ready for the operation, and consequently it usually happens that some time elapses before the remedy can be applied. Of course we all know that delay in such matters frequently proves fatal, and it was of this undoubtedly that Dr. Moser was thinking when he invented the tiny, portable apparatus which he calls the *crayon feu*, and which is so simply constructed that it can be used alike by physicians, travellers, hunters, or indeed any one who has either been bitten himself or who is required to treat another person.

This little instrument consists of a pencil made of some peculiar composition which ignites instantly when a match is applied to it and becomes red-hot while the patient's wound is being washed. The point of the pencil is then introduced directly into the wound, and the cauterization is performed in an instant. The patient merely experiences a slight sensation of being burned, as the operation is over before he is able to feel any definite pain. A little wooden or metal cover is placed over the pencil when it is not in use, and at the other end is a small receptacle for the particular kind of wax matches which are required to light it.

The *crayon feu* is indeed *multum in parvo* and can be carried in the vest pocket. Medical men, scientific societies, and all public administrations in Paris have given it a warm welcome—no pun is here intended—and their example has been followed by a host of others, while Dr. Moser himself, is looked upon as a veritable benefactor to humanity.

No less interesting are the curious experiments recently made by a Hungarian, M. Kerdig, by means of a combustible substance which is undoubtedly destined to be used at some future time for illuminating purposes.

M. Kerdig begins by placing upon a table a number of lamps filled with this fluid, which, indeed, gives forth a most brilliant light. He then announces to the interested spectators that it is in no danger whatever of catching fire or exploding, and in order to illustrate this fact so that even the veriest skeptic shall believe, he pours a quantity of the liquid upon his hat and calmly sets fire to it. A mass of lurid flame rises instantly almost to the ceiling, but M. Kerdig, in no wise disconcerted, places his hat coolly upon his head, and waits until the flame gradualty dies out. He then exhibits the hat triumphantly to the audience—it is uninjured. He next sets fire to the floor, then to his handkerchief, saturated with the substance, and finally goes so far as to pour some of it into the palm of his hand and light it; but the floor, the handkerchief and the hand are all alike unharmed.

Of course all this appears most extraordinary at first sight, but a little careful investigation is in this case, as in many others, capable of reducing mountains to mole hills. The vapor of M. Kerdig's mineral substance possesses considerable expansive force, so that in reality it is the vapor which burns and not the liquid. The latter being at a very low temperature, produces no sensation of heat upon the hand, notwithstanding the flame above.

Now, I suppose you would like to know of what this interesting product consists. M. Kerdig says that it is a very volatile essence of naptha, to which is added a compound of various evaporating substances. Other people, however, affirm that it is a product derived from natural oils recently discovered in Hungary, which, when properly distilled, results in a peculiar substance, very volatile, and, what is of still more importance, very cheap. A faint odor of petroleum pervades it, accompanied by a slight aromatic fragrance, and when spread upon the hand a sensation of cold is felt.

We have just received intelligence from the south of France of the terrible ravages made upon the olive crops this season by an insect designated by the entomologists as the *Dacusoleæ*. It is a little gray fly, with several legs, and long yellow antennæ. There are two generations of them every year, one appearing in July, the other in September. The eggs are deposited in the fruit, and the larva, which resembles a little yellowish-white maggot, consumes the pulp, intersecting it with tiny passages. The adult leaves the olive and makes its way to the ground, where it is transformed into a chrysalis and remains buried during the winter months.

Speaking upon agricultural topics reminds me of an unprecedented phenomenon which has just occurred in one of the districts of Jonzac. Upon the estate of a certain M. Delaume, who lives at Sèville, there is a grape vine which for five years has been infested with phylloxera, and the greater part of whose branches have borne nothing whatever—neither leaves nor fruit during that period. But a most unforeseen and extraordinary thing suddenly happened. From one branch, which has hitherto been looked upon as quite dead, has sprung a magnificent grape vine, well formed, and of a beautiful, dark green color. No one, as yet, has been able to explain this singular occurrence.

Still less can we account for another most remarkable event, a description of which I lately read in a Hungarian paper. A criminal, it seems, had been hanged, and the physician in attendance declared that life was quite extinct. An autopsy was subsequently made upon the body, and the latter subjected to the action of a strong galvanic current. Within the space of two hours, signs of life were distinctly observed. The dead man recovered his senses completely, but succumbed, on the second day following, to cerebral congestion.

If this account be true, we cannot too greatly encourage the use of electricity as a resuscitative and vital agent, nor can we fail to admit that the present age is one of unparalleled phenomena. COSMOS.

LAWS OF THE DISENGAGEMENT OF ELECTRICITY BY PRESSURE IN TOURMALINE.—The authors announce the following laws as resulting from their experiments:—The two ends of a tourmaline evolve quantities of electricity respectively equal, but of opposite signs. The quantity liberated by a certain increase of pressure is opposite in its sign, but equal to that produced by an equal decrease of pressure. This quantity is proportional to the variation of the pressure, independent of the length of the tourmaline, and for one and the same variation of pressure per unit of surface it is proportional to the surface.—M M. Jacques and Pierre Curie.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

SATURDAY, MARCH 12, 1881.

INSANITY VERSUS CIVILIZATION.

It is interesting to note the steady progress made by Alienists in solving the many difficult problems which appear to underlie the practice of their profession, and we would give full credit to those who, in a purely scientific spirit, are building a foundation on which a system of treatment for mental diseases may be erected, which shall accord with modern anatomical discovery and the latest theories which have been developed by a careful study of insanity in all its forms.

The last number of the "*Journal of Nervous and Mental Diseases*" may be studied with advantage by those who would gather a few opinions expressed by those who "minister to a mind diseased." In the first place, we have the authority of Dr. J. S. Jewell for stating that insanity is on the increase, and must still increase with the advance of civilization. In this opinion he is confirmed by Professor W. Erb, of Leipzig, and others. Among the reasons advanced for alleging that the advance of civilization is favorable to an increase in nervous and mental diseases, it is stated, that the nervous systems of highly cultivated and refined individuals among civilized people are more complex and refined in structure and more delicate in susceptibility and action, at least in their higher parts, than the nervous systems of savages. As civilization advances, the occupations increase which imply a cultivation of the sensibilities, more especially those comprehended under the sense of beauty. A relatively large number of persons give themselves to the study and practice of art in its various forms, to polite literature, and to sedentary occupations. The more a part of the nervous system is used the more extended its development. In highly civilized communities there is a constant tendency to a loss of balance in nerve development, in which the *sensitive* side of the nervous system preponderates over the motor part of the same. Now, all disturbances of symmetry or balance in development tend toward disease; they do not constitute disease, but verge in that direction. This state of things is the result of advancing civilization, and involve a world of minor consequences, both for the weal and woe of the people.

Such is the substance of Dr. Jewell's views, who also charges the system of education in public schools with being the cause of increasing the number of cases of insanity, by breaking up the "*nerve health*" of youths. This remark applies equally to the course of study in Colleges and Universities, and the overworked student in hundreds of cases obtains his degree at the expense of loss of health, and retires with general nervous and brain exhaustion, and afflicted with melancholia, hysteria, vascular irregularities, cerebral congestion, neuralgias and other disorders of the same character.

Space will not permit us to describe the many forms in which the adult, in civilized life, courts the approach of the various forms of insanity; but they can be easily surmised, and are often referred to in articles treating on this subject.

We admit, with Dr. Jewell, that the higher developments of civilized life may produce a higher strain on the nervous system which may lead to more frequent cases of its derangement; but we think he draws too wide a parallel when he makes a distinction between our present modes of existence and actual savage life. When speaking of the increase of insanity, it is presumed reference is made to a period covering, perhaps, the last fifty years. Such being the case, we think Dr. Jewell has hardly done justice to the subject, by omitting the many mitigating circumstances attending an advanced civilization, which certainly alleviate many of the mental strains spoken of by him.

Within the last fifty years, the hours of labor have been curtailed both in manufactories and among the industrial classes in cities. Stores which at one time were open until midnight are now closed at 7 P. M. Means of recreation and amusements which until recently were monopolized by a few, are now enjoyed by the millions. Improved methods of transit now enable citizens to enjoy their evenings after the hours of labor, strolling upon grassy meadows or upon the shores of the ocean. Literature of an entertaining character is also now produced so cheaply as to make its use universal. The laws of hygiene are also at this present day better understood, and, by perfecting man's physical condition, instill fresh energy into his mental powers.

We thus find that, so far from all the conditions attending an advanced civilization being favorable to

insanity, many have a tendency to promote the most perfect mental and physical development.

If the Alienist would solve the problem attending the increase of cases of insanity, we would direct him to other sources of the evil than that of civilization; let him probe the open and hidden vices of great cities; let him calculate the effect of the indiscriminate use of alcoholic liquors and the pernicious abuse of potent drugs. We regard opium, tobacco, chloral and sewer gas as some of the offending agents which weaken and debilitate the mental powers, rather than the mild educational cause of our public schools or the attending circumstances of student-life.

Dr. Jewell himself admits the destructive effects of these agents upon the nervous system, but they are classed as due to the influence of civilization. This we think an error, as they are connected with vices of a debased life; and although insanity may be on the increase, we consider it is far from conclusive that to civilization we should attribute the primary cause.

SCIENTIFIC SOCIETIES IN WASHINGTON, D. C.

THE BIOLOGICAL SOCIETY.—Three papers were read at the last meeting, Friday, Feb. 25, as follows: A Description of Pronuba yuccasella, by Prof. C. V. Riley; The Hall Collection of Fossils from New York, by Prof. C. A. White; and Suctorial Prehension in the Animal Kingdom, by Mr. Smiley. Professor Riley's paper was a revision of his communications before the American Association at St. Louis and in other places, concerning a moth, the *Pronuba yuccasella*, which not only deposits its eggs in the capsules of the Yucca, but which is also indispensable to the fertilization of the ovaries of that plant. It was remarked by Mr. Lester F. Ward, in commenting upon the paper, that we have here the most wonderful example of commensualism. Professor White is in charge of the duplicate set from the Hall Collection of Fossils sent to the National Museum. His remarks were a brief description of them as they now appear. There are about 1500 entries, and they represent nearly all the types in the Collection of the American Museum. Mr. Smiley's paper was a description of suctorial organs in the various divisions of the animal kingdom. These organs have in different circumstances, three functions, locomotion, anchoring and the seizure of prey. The author has bestowed a great deal of care on his communication and brought together a valuable mass of material.

THE ANTHROPOLOGICAL SOCIETY.—The Society met in the main hall of the National Medical College, Major J. W. Powell in the chair. The following papers were read: Amphibious Aborigines of Alaska, by Ivan Petroff; The Evolution of Marriage Ceremonies and Their Import, by Dr. A. F. A. King. Mr. Petroff described his experience among the shore Innuit population of Alaska, from the lower peninsula north to the Yukon mouth. There is water and marsh, mud and swamp everywhere, and the heavens swell the mass by their contribution of fog, rain, snow and sleet. The natives are enveloped in this watery environment the year round and thrive upon it. They even drink enormous quantities of it, not excepting the salt water of the bays and fiords, in their long fishing journeys, Doctor King's paper was an argument to prove that the progress of civilization had the tendency to set aside the laws of sexual relations which exist in a state of nature, such as the survival of the fittest, the observance of natural periods, and sexual selection. The paper was discusssed by Major Powell and Mr. Ward.

ACTION OF AN INTERMITTENT BEAM OF RADIANT HEAT UPON GASEOUS MATTER.*

By JOHN TYNDALL, F. R. S.

The Royal Society has already done me the honor of publishing a long series of memoirs on the interaction of radiant heat and gaseous matter. These memoirs did not escape criticism. Distinguished men, among whom the late Professor Magnus and the late Professor Buff may be more specially mentioned, examined my experiments, and arrived at results different from mine. Living workers of merit have also taken up the question; the latest of whom,† while justly recognizing the extreme difficulty of the subject, and while verifying, so far as their experiments reach, what I had published regarding dry gases, find me to have fallen into what they consider grave errors in my treatment of vapors.

None of these investigators appear to me to have realized the true strength of my position in its relation to the objects I had in view. Occupied for the most part with details, they have failed to recognize the stringency of my work as a whole, and have not taken into account the independent support rendered by the various parts of the investigation to each other. They thus ignore verifications, both general and special, which are to me of conclusive force. Nevertheless, thinking it due to them and me to submit the questions at issue to a fresh examination, I resumed, some time ago the threads of the inquiry. The results shall, in due time, be communicated to the Royal Society; but meanwhile, I would ask permission to bring to the notice of the Fellows a novel mode of testing the relations of radiant heat to gaseous matter, whereby singularly instructive effects have been obtained.

After working for some time with the thermopile and galvanometer, it occurred to me several weeks ago that the results thus obtained might be checked by a more direct and simple form of experiment. Placing the gases and vapors in diathermanous bulbs, and exposing the bulbs to the action of radiant heat, the heat absorbed by different gases and vapors ought, I considered, to be rendered evident by ordinary expansion. I devised an apparatus with a view of testing this idea. But, at this point, and before my proposed gas thermometer was constructed, I became acquainted with the ingenious and original experiments of Mr. Graham Bell, wherein musical sounds are obtained through the action of an intermittent beam of light upon solid bodies.

From the first, I entertained the opinion that these singular sounds were caused by rapid changes of temperature, producing corresponding changes of shape and volume in the bodies impinged upon by the beam. But if this be the case, and if gases and vapors really absorb radiant heat, they ought to produce sounds more intense than those obtainable from solids. I pictured every stroke of the beam responded to by a sudden expansion of the absorbent gas, and concluded that when the pulses thus excited followed each other with sufficient rapidity, a musical note must be the result. It seemed plain, moreover, that by this new method many of my previous results might be brought to an independent test. Highly diathermanous bodies, I reasoned, would produce faint sounds; while highly athermanous bodies would produce loud sounds; the strength of the sound being, in a sense, a measure of the absorption. The first experiment made, with a view of testing this idea, was executed in the presence of Mr. Graham Bell;‡ and the result was in exact accordance with what I had foreseen.

The inquiry has been recently extended so as to em-

*Proceedings of the Royal Society.

† MM. Lecher and Pernter, "Philosophical Magazine," January, 1881. "Sitzb. der K. Akad. der Wissensch. in Wien," July, 1880.

‡On the 20th of November: see "Journal of the Society of Telegraph Engineers," December 8, 1880.

brace most of the gases and vapors employed in my former researches. My first source of rays was a Siemens' lamp connected with a dynamo-machine, worked by a gas engine. A glass lens was used to concentrate the rays, and afterwards two lenses. By the first the rays were rendered parallel, while the second caused them to converge to a point about seven inches distant from the lens. A circle of sheet zinc provided first with radial slits and afterwards with teeth and interspaces, cut through it, was mounted vertically on a whirling table, and caused to rotate rapidly across the beam near the focus. The passage of the slits produced the desired intermittence,* while a flask containing the gas or vapor to be examined received the shocks of the beam immediately behind the rotating disc. From the flask a tube of india-rubber, ending in a tapering one of ivory or box wood, led to the ear, which was thus rendered keenly sensitive to any sound generated within the flask. Compared with the beautiful apparatus of Mr. Graham Bell, the arrangement here described is rude; it is, however, effective.

With this arrangement the number of sounding gases and vapors was rapidly increased. But I was soon made aware that the glass lenses withdrew from the beam its effectual rays. The silvered mirrors employed in my previous researches were therefore invoked; and with them, acting sometimes singly and sometimes as conjugate mirrors, the curious and striking results which I have now the honor to submit to society were obtained.

Sulphuric ether, formic ether, and acetic ether being placed in bulbous flasks,† their vapors were soon diffused in the air above the liquid. On placing these flasks, whose bottoms only were covered by the liquid, behind the rotating disc, so that the intermittent beam passed through the vapor, loud musical tones were in each case obtained. These are known to be the most highly absorbent vapors which my experiments revealed. Chloroform and bisulphide of carbon, on the other hand, are known to be the least absorbent, the latter standing near the head of diathermanous vapors. The sounds extracted from these two substances were usually weak and sometimes barely audible, being more feeble with the bisulphide than with the chloroform. With regard to the vapors of amylene, iodide of ethyl, iodide of methyl and benzol, other things being equal, their power to produce musical tones appeared to be accurately expressed by their ability to absorb radiant heat.

It is the vapor, and not the liquid, that is effective in producing the sounds. Taking, for example, the bottles in which my volatile substances are habitually kept, I permitted the intermittent beam to impinge upon the liquid in each of them. No sound was in any case produced, while the moment the vapor-laden space above an active liquid was traversed by the beam, musical tones made themselves audible.

A rock-salt cell filled entirely with a volatile liquid, and subjected to the intermittent beam, produced no sound. This cell was circular and closed at the top. Once, while operating with a highly athermanous substance, a distinct musical note was heard. On examining the cell, however, a small bubble was found at its top. The bubble was less than a quarter of an inch in diameter, but still sufficient to produce audible sounds. When the cell was completely filled, the sounds disappeared.

It is hardly necessary to state that the pitch of the note obtained in each case is determined by the velocity of rotation. It is the same as that produced by blowing against the rotating disc and allowing its slits to act like the perforations of a syren.

Thus, as regards vapors, prevision has been justified by experiment. I now turn to gases. A small flask, after having been heated in the spirit lamp so as to detach all moisture from its sides, was carefully filled with dried air. Placed in the intermittent beam it yielded a musical note, but so feeble as to be heard only with attention. Dry oxygen and hydrogen behaved like dry air. This agrees with my former experiments, which assigned a hardly sensible absorption to these gases. When the dry air was displaced by carbonic acid, the sound was far louder than that obtained from any of the elementary gases. When the carbonic acid was displaced by nitrous oxide, the sound was much more forcible still, and when the nitrous oxide was displaced by olefiant gas, it gave birth to a musical note which, when the beam was in good condition, and the bulb well chosen, seemed as loud as that of an ordinary organ pipe.* We have here the exact order in which my former experiments proved these gases to stand as absorbers of radiant heat. The amount of the absorpti n and the intensity of the sound go hand in hand.

A soap bubble blown with nitrous oxide, or olefiant gas, and exposed to the intermittent beam produced no sound, no matter how its size might be varied. The pulses obviously expended themselves upon the flexible envelope, which transferred them to the air outside.

But a film thus impressionable to impulses on its interior surface, must prove at least equally sensible to sonorous waves impinging on it from without. Hence, I inferred, the eminent suitability of soap bubbles for sound lenses. Placing a "sensitive flame" some feet distant from a small sounding reed, the pressure was so arranged that the flame burnt tranquilly. A bubble of nitrous oxide (sp. gr. 1·527) was then blown, and placed in front of the reed. The flame immediately fell and roared, and continued agitated as long as the lens remained in position. A pendulous motion could be imparted to the bubble, so as to cause it to pass to and fro in front of the reed. The flame responded, by alternately roaring and becoming tranquil, to every swing of the bubble. Nitrous oxide is far better for this experiment than carbonic acid, which speedily ruins its envelope.

The pressure was altered so as to throw the flame, when the reed sounded, into violent agitation. A bubble blown with hydrogen (sp. gr. 0·069) being placed in front of the reed, the flame was immediately stilled. The ear answers instead of the flame.

In 1839, I proved gaseous ammonia to be extremely impervious to radiant heat. My interest in its deportment when subjected to this novel test was therefore great. Placing a small quantity of liquid ammonia in one of the flasks, and warming the liquid slightly, the intermittent beam was sent through the space above the liquid. A loud musical note was immediately produced. By the proper application of heat to a liquid the sounds may be always intensified. The ordinary temperature, however, suffices in all the cases thus far referred to.

In this relation the vapor of water was that which interested me most, and as I could not hope that at ordinary temperatures it existed in sufficient amount to produce audible tones, I heated a small quantity of water in a flask almost up to its boiling-point. Placed in the intermitten beam, I heard—I avow with delight

* When the disc rotates the individual slits disappear, forming a hazy zone through which objects are visible. Throwing by the clean hand, or better still by white paper, the beam back upon the disc, it appears to stand still, the slips forming so many dark rectangles. The reason is obvious, but the experiment is a very beautiful one.

I may add that when I stand with open eyes in the flashing beam, at a definite velocity of recurrence, subjective colors of extraordinary gorgeousness are produced. With slower or quicker rates of rotation the colors disappear. The flashes also produce a giddiness, sometimes intense enough to cause me to grasp the table to keep myself erect.

† I have employed flasks measuring from 8 inches to ¾ths of an inch in diameter. The smallest flask, which had a stem with a bore of about ⅛th of an inch in diameter, yielded better effects than the largest. Flasks from 2 to 3 inches in diameter yield good results. Ordinary test-tubes also answer well.

* With conjugate mirrors the sounds with olefiant gas are readily obtained at a distance of twenty yards from the lamp. I hope to be able to make a candle flame effective in these experiments.

—a powerful musical sound produced by the aqueous vapor.

Small wreaths of haze, produced by the partial condensation of the vapor in the upper and cooler air of the flask, were, however, visible in this experiment; and it was necessary to prove that this haze was not the cause of the sound. The flask was, therefore, heated by a spirit-flame beyond the temperature of boiling water. The closest scrutiny by a condensed beam of light then revealed no trace of cloudiness above the liquid. From the perfectly invisible vapor, however, the musical sound issued, if anything, more forcible than before. I placed the flask in cold water until its temperature was reduced from about 90° to 10° C., fully expecting that the sound would vanish at this temperature; but not withstanding the tenuity of the vapor, the sound extracted from it was not only distinct but loud.

Three empty flasks, filled with ordinary air, were placed in a freezing mixture for a quarter of an hour. On being rapidly transferred to the intermittent beam, sounds much louder than those obtainable from dry air were produced.

Warming these flasks in the flame of a spirit-lamp until all visible humidity has been removed, and afterwards urging dried air through them, on being placed in the intermittent beam the sotum in each case was found to have fallen almost to silence.

Sending, by means of a glass tube, a puff of breath from the lungs into a dried flask, the power of emitting sound was immediately restored.

When, instead of breathing into a dry flask, the common air of the laboratory was urged through it, the sounds became immediately intensified. I was by no means prepared for the extraordinary delicacy of this new method of testing the athermancy and diathermancy of gases and vapors, and it cannot be otherwise than satisfactory to me to find that particular vapor, whose alleged deportment towards radiant heat has been most strenuously denied, affirming thus audibly its true character.

After what has been stated regarding aqueous vapor, we are prepared for the fact that an exceedingly small percentage of any highly athermanous gas diffused in air suffices to exalt the sounds. An accidental observation will illustrate this point. A flask was filled with coal-gas and held bottom upwards in the intermittent beam. The sounds produced were of a force corresponding to the known absorptive energy of coal-gas. The flask was then placed upright, with its mouth open upon a table, and permitted to remain there for nearly an hour. On being restored to the beam, the sounds produced were far louder than those which could be obtained from common air.

Transferring a small flask or a test-tube from a cold place to the intermittent beam, it is sometimes found to be practically silent for a moment, after which the sounds become distinctly audible. This I take to be due to the vaporisation by the calorific beam of the thin film of moisture adherent to the glass.

My previous experiments having satisfied me of the generality of the rule that volatile liquids andtheir vapors absorb the same rays, I thought it probable that the introduction of a thin layer of its liquid, even in the case of a most energetic vapor, would detach the effective rays, and thus quench the sounds. The experiment was made, and the conclusion verified. A layer of water, formic ether, sulphuric ether, or acetic ether, ⅛th of an inch in thickness, rendered the transmitted beam powerless to produce any musical sound. These liquids being transparent to light, the efficient rays which they intercepted must have been those of obscure heat.

A layer of bisulphide of carbon about ten times the thickness of the transparent layers just referred to, and rendered opaque to light by dissolved iodine, was interposed in the path of the intermittent beam. It produced hardly any diminution of the sounds of the more active vapors—a further proof that it is the invisible heat rays, to which the solution of iodine is so eminently transparent, that are here effectual.

Converting one of the small flasks used in the foregoing experiments into a thermometer bulb, and filling it with various gases in succession, it was found that with those gases which yielded a feeble sound, the displacement of a thermometric column associated with the bulb was slow and feeble, while with those gases which yielded loud sounds, the displacement was prompt and forcible.

Received January 10, 1881.

FURTHER EXPERIMENTS.

Since the handing in of the foregoing note, on the 3rd of January, the experiments have been pushed forward; augmented acquaintance with the subject serving only to confirm my estimate of its interest and importance.

All the results described in my first note have been obtained in a very energetic form with a battery of sixty Grove's cells.

On the 4th of January I chose for my source of rays a powerful lime-light, which, when sufficient care is taken to prevent the pitting of the cylinder, works with admirable steadiness and without any noise. I also changed my mirror for one of shorter focus, which permitted a nearer approach to the source of rays. Tested with this new reflector the stronger vapors rose remarkably in sounding power.

Improved manipulation was, I considered, sure to extract sounds from rays of much more moderate intensity than those of the lime-light. For this light, therefore, a common candle flame was substituted. Received and thrown back by the mirror, the radiant heat of the candle produced audible tones in all the stronger vapors.

Abandoning the mirror and bringing the candle close to the rotating disc, its direct rays produced audible sounds.

A red-hot coal, taken from the fire and held close to the rotating disc produced forcible sounds in a flask at the other side.

A red-hot poker, placed in the position previously occupied by the coal, produced strong sounds. Maintaining the flask in position behind the rotating disc, amusing alternations of sound and silence accompanied the alternate introduction and removal of the poker.

The temperature of the iron was then lowered till its heat just ceased to be visible. The intermittent invisible rays produced audible sounds.

The temperature was gradually lowered, being accompanied by a gradual and continuous diminution of the sound. When it ceased to be audible the temperature of the poker was found to be below that of boiling water.

As might be expected from the foregoing experiments, an incandescent platinum spiral, with or without the mirror, produced musical sounds. When the battery power was reduced from ten cells to three, the sounds, though enfeebled, were still distinct.

My neglect of aqueous vapor had led me for a time astray in 1859, but before publishing my results I had discovered my error. On the present occasion this omnipresent substance had also to be reckoned with. Fourteen flasks of various sizes, with their bottoms covered with a little sulphuric acid, were closed with ordinary corks and permitted to remain in the laboratory from the 23d of December to the 4th of January. Tested on the latter day with the intermittent beam, half of them emitted feeble sounds, but half were silent. The sounds were undoubtedly due, not to dry air, but to traces of aqueous vapor.

An ordinary bottle, containing sulphuric acid for laboratory purposes, being connected with the ear and

placed in the intermittent beam, emitted a faint, but distinct, musical sound. This bottle had been opened two or three times during the day, its dryness being thus vitiated by the mixture of a small quantity of common air. A second similar bottle, in which sulphuric acid had stood undisturbed for some days, was placed in the beam: the dry air above the liquid proved absolutely silent.

On the evening of January the 7th, professor Dewar handed me four flasks treated in the following manner. Into one was poured a small quantity of strong sulphuric acid; into another a small quantity of Nordhausen sulphuric acid; in a third were placed some fragments of fused chloride of calcium; while the fourth contained a small quantity of phosphoric anhydride. They were closed with well fitting india-rubber stoppers, and permitted to remain undisturbed throughout the night. Tested after twelve hours, each of them emitted a feeble sound, the flask last mentioned being the strongest. Tested again six hours later, the sound had disappeared from three of the flasks, that containing the phosphoric anhydride alone remaining musical.

Breathing into a flask partially filled with sulphuric acid instantly restores the sounding power, which continues for a considerable time. The wetting of the interior surface of the flask with sulphuric acid always enfeebles, and sometimes destroys the sound.

A bulb, less than a cubic inch in volume, and containing a little water, lowered to the temperature of melting ice, produces very distinct sounds. Warming the water in the flame of a spirit-lamp, the sound becomes greatly augmented in strength. At the boiling temperature the sound emitted by this small bulb* is of extraordinary intensity.

These results are in accord with those obtained by me nearly nineteen years ago, both in reference to air and to aqueous vapor. They are in utter disaccord with those obtained by other experimenters, who have ascribed a high absorption to air and none to aqueous vapor.

The action of aqueous vapor being thus revealed, the necessity of thoroughly drying the flasks, when testing other substances, becomes obvious. The following plan has been found effective. Each flask is first heated in the flame of a spirit-lamp till every visible trace of internal moisture has disappeared, and it is afterwards raised to a temperature of about 400° C. While the flask is still hot, a glass tube is introduced into it and air freed from carbonic acid by caustic potash, and from aqueous vapor by sulphuric acid, is urged through the flask until it is cool. Connected with the ear-tube, and exposed immediately to the intermittent beam, the attention of the ear, if I may use the term, is converged upon the flask. When the experiment is carefully made, dry air proves as incompetent to produce sound as to absorb radiant heat.

In 1868 I determined the absorptions of a great number of liquids whose vapors I did not examine. My experiments having amply proved the parallelism of liquid and vaporous absorption, I held undoubtingly twelve years ago that the vapor of cyanide of ethyl and of acetic acid would prove powerfully absorbent. This conclusion is now easily tested. A small quantity of either of these substances, placed in a bulb a cubic inch in volume, warmed, and exposed to the intermittent beam, emits a sound of extraordinary power.

I also tried to extract sounds from perfumes, which I had proved in 1861 to be absorbers of radiant heat. I limit myself here to the vapors of patchouli and cassia, the former exercising a measured absorption of 30, and the latter an absorption of 109. Placed in dried flasks, and slightly warmed, sounds were obtained from both these substances, but the sound of cassia was much louder than patchouli.

* In such bulbs even bisulphide of carbon vapor may be so nursed as to produce sounds of considerable strength.

Many years ago I had proved tetrachloride of carbon to be highly diathermanous. Its sounding power is as feeble as its absorbent power.

In relation to colliery explosions, the deportment of marsh-gas was of special interest. Professor Dewar was good enough to furnish me with a pure sample of this gas. The sounds produced by it, when exposed to the intermittent beam, were very powerful.

Chloride of methyl, a liquid which boils at the ordinary temperature of the air, was poured into a small flask, and permitted to displace the air within it. Exposed to the intermittent beam, its sound was similar in power to that of marsh-gas.

The specific gravity of marsh gas being about half that of air, it might be expected that the flask containing it, when left open and erect, would soon get rid of its contents. This, however, is not the case. After a considerable interval, the film of this gas clinging to the interior surface of the flask was able to produce sounds of great power.

A small quantity of liquid bromine being poured into a well-dried flask, the brown vapor rapidly diffused itself in the air above the liquid. Placed in the intermittent beam, a somewhat forcible sound was produced. This might seem to militate against my former experiments, which assigned a very low absorptive power to bromine vapor. But my former experiments on this vapor were conducted with obscure heat; whereas, in the present instance, I had to deal with the radiation from incandescent lime, whose heat is, in part, luminous. Now, the color of the bromine vapor proves it to be an energetic absorber of the luminous rays; and to them, when suddenly converted into thermometric heat in the body of the vapor, I thought the sounds might be due.

Between the flash containing the bromine and the rotating disc I therefore placed an empty glass cell: the sounds continued. I then filled the cell with transparent bisulphide of carbon: the sounds still continued. For the transparent bisulphide I then substituted the same liquid saturated with dissolved iodine. This solution cut off the light, while allowing the rays of heat free transmission: the sounds were immediately stilled.

Iodine vaporised by heat in a small flask yielded a forcible sound, which was not sensibly affected by the interposition of transparent bisulphide of carbon, but which was completely quelled by the iodine solution. It might indeed have been foreseen that the rays transmitted by the iodine as a liquid would also be transmitted by its vapor, and thus fail to be converted into sound.*

To complete the argument:—While the flask containing the bromine vapor was sounding in the intermittent beam, a strong solution of alum was interposed between it and the rotating disc. There was no sensible abatement of the sounds with either bromine or iodine vapor.

In these experiments the rays from the lime-light were converged to a point a little beyond the rotating disc. In the next experiment they were rendered parallel by the mirror, and afterwards rendered convergent by a lens of ice. At the focus of the ice lens the sounds were extracted from both bromine and iodine vapor. Sounds were also produced after the beam had been sent through the alum solution and the ice lens conjointly.

With a very rude arrangement I have been able to hear the sounds of the more active vapors at a distance of 100 feet from the source of rays.

Several vapors other than those mentioned in this abstract have been examined, and sounds obtained from all of them. The vapors of all compound liquids will, I doubt not, be found sonorous in the intermittent beam. And, as I question whether there is an absolutely diathermanous substance in nature, I think it probable that

* I intentionally use this phraseology.

even the vapors of elementary bodies, including the elementary gases, when more strictly examined, will be found capable of producing sounds.

THE UNITY OF NATURE.

By the Duke of Argyll.

VI.

(*Continued from page* 103.)

ON THE MORAL CHARACTER OF MAN, CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

In dealing with this question, it is a comfort to remember that we are in possession of analogies deeply seated in the constitution and in the course of Nature. It is quite possible to assign to Intuition or to Instinct the place and rank which really belongs to it, and to assign also to what is called Experience the functions which are unquestionably its own. There is no sense or faculty of the mind which does not gain by education—not one which is independent of those processes of development which result from its contact with the external world. But neither is there any sense or faculty of the mind which starts unfurnished with some one or more of those intuitive perceptions with which all education and all development must begin. Just as every exercise of reason must be founded on certain axioms which are self-evident to the logical faculty, so all other exercises of the mind must start from the direct perception of some rudimentary truths. It would be strange indeed if the moral faculty were any exception to this fundamental law. This faculty in its higher conditions, such as we see it in the best men in the most highly civilized communities, may stand at an incalulable distance from its earliest and simplest condition, and still more from its lowest condition, such as we see it in the most degraded races of mankind. But this distance has been reached from some starting-point, and at that starting-point there must have been some simple acts or dispositions to which the sense of obligation was instinctively attached. And beyond all question this is the fact. All men do instinctively know what gives pleasure to themselves, and therefore also what gives pleasure to other men. Moreover, to a very large extent, the things which give them pleasure are the real needs of life, and the acquisition or enjoyment of these is not only useful but essential to the well-being or even to the very existence of the race. And as Man is a social animal by nature, with social instincts at least as innate as those of the Ant or the Beaver or the Bee, we may be sure that there were and are born with him all those intuitive perceptions and desires which are necessary to the growth and unfolding of his powers. And this we know to be the fact, not only as a doctrine founded on the unities of Nature, but as a matter of universal observation and experience. We know that without the Moral Sense Man could not fulfill the part which belongs to him in the world. It is as necessary in the earliest stages of the Family and of the Tribe, as it is in the latest developments of the State and of the Church. It is an element without which nothing can be done—without which no man could trust another, and, indeed, no man could trust himself. There is no bond of union among men—even the lowest and the worst—which does not involve and depend upon the sense of obligation. There is no kind of brotherhood or association for any purpose which could stand without it. As a matter of fact, therefore, and not at all as a matter of speculation, we know that the Moral Sense holds a high place as one of the necessary conditions in the development of Man's nature, in the improvement of his condition, and in the attainment of that place which may yet lie before him in the future of the world. There are other sentiments and desires, which, being as needful, are equally instinctive. Thus, the desire of communicating pleasure to others is one of the instincts which is as universal in Man as the desire of communicating knowledge. Both are indeed branches of the same stem—off-shoots from the same root. The acquisition of knowledge, to which we are stimulated by the instinctive affections of curiosity and of wonder, is one of the greatest of human pleasures, and the desire we have to communicate our knowledge to others is the great motive-force on which its progress and accumulation depend. The pleasure which all men take, when their dispositions are good, in sharing with others their own enjoyments, is another feature quite as marked and quite as innate in the character of Man. And if there is any course of action to which we do instinctively attach the sentiment of moral approbation, it is that course of action which assumes that our own desires, and our own estimates of good, and the standard by which we ought to judge of what is due to and is desired by others. The social instincts of our nature must, therefore, naturally and intuitively indicate benevolence as a virtuous, and malevolence as a vicious disposition; and, again, our knowledge of what is benevolent and what is malevolent is involved in our own instinctive sense of what to us is good, and of what to us is evil. It is quite true that this sense may be comparatively low or high, and consequently that the standard of obligation which is founded upon it may be elementary and nothing more. Those whose own desires are few and rude, and whose own estimates of good are very limited, must of course form an estimate correspondingly poor and scant of what is good for, and of what is desired by, others. But this exactly corresponds with the facts of human nature. This is precisely the variety of unity which its phenomena present. There are no men of sane mind in whom the Moral Sense does not exist; that is to say, there are no men who do not attach to some actions or other the sentiment of approval, and to some other actions the opposite sentiment of condemnation. On the other hand, the selection of the particular actions to which these different sentiments are severally attached is a selection immensely various; there being, however, this one common element in all—that the course of action to which men do by instinct attach the feeling of moral obligation, is that course of action which is animated by the feeling that their own desires and their own estimate of good is the standard by which they must judge of what is due by them to others, and by others to themselves.

And here we stand at the common point of departure from which diverge the two great antagonistic schools of ethical philosophy. On the other hand in the intuitive and elementary character which we have assigned to the sentiment of obligation, considered in itself, we have the fundamental position of that school which asserts an independent basis of morality; whilst, on the other hand, in the elementary truths which we have assigned to the Moral Sense as its self-evident apprehensions, we have a rule which corresponds, in one aspect at least, to the fundamental conception of the Utilitarian school. For the rule which connects the idea of obligation with conduct tending to the good of others, as tested by our own estimate of what is good for ourselves, is a rule which clearly brings the basis of morality into very close connection with the practical results of conduct. Accordingly, one of the ablest modern advocates of the Utilitarian system has declared that "in the golden rule of Jesus of Nazareth we read the complete spirit of the ethics of Utility. To do as you would be done by, and to love your neighbor as yourself, constitute the ideal perfection of Utilitarian morals."[2]

This may well seem a strange and almost a parodoxical result to those who have been accustomed to consider the Utilitarian theory not so much a low standard of morals, as an idea which is devoid altogether of that ele-

[2] J. S. Mill: "Utilitarianism," pp. 24, 25.

ment in which the very essence of morality consists. But it is a result due to these two causes—first, that under the fire of controversy Utilitarians have been obliged to import into the meaning of their words much that does not really belong to them; and secondly, to the fact, that when this essential alteration has been made, then the theory, or rather the portion of it which remains, does represent one very important aspect of a very complex truth.

It will be well to examine a little more closely the different ways in which these two causes operate.

In the first place, as regards the ambiguities of language, a moment's consideration will convince us that the word "utility" has, in its proper and primary signification, nothing whatever of the ethical meaning which is attached to it in the Utilitarian theory of morals. In its elementary signification the useful is simply the serviceable. It is curious to observe that this last word has no ethical savor about it. On the contrary, it is associated rather with the lower uses than with the higher of conduct. If this be objected to as preventing the two words from being really the equivalent of each other, then at least let it be recognized that utility must be divested of its ethical associations before it can be set up as an ethical test. If utility is first assumed to be the equivalent of goodness, it becomes of course a mere play on words to represent usefulness as the criterion of virtue. If we are to conduct our analysis correctly, we must expel from utility every adventitious element of meaning. The usefulness of a thing means nothing more than its conduciveness to some purpose. But it may be any purpose,—morally good, or morally bad, or morally indifferent. The boot-jack, the thumb-screw, and the rack are all useful machines for the purpose of producing torture on the victim, and for the purpose, too, of giving to the torturers that pleasure or satisfaction which wicked men find in tyranny or revenge. The words "good" and "bad" are themselves often used in a secondary and derivative sense, which, like "useful," may be destitute of any ethical meaning. A good thumb-screw would mean an implement well adapted to produce the most exquisite pain. A good torture may mean a torture well calculated to gratify the savage sentiment of revenge. In like manner, although not to the same extent, the words "right" and "wrong" are often used with no ethical element of meaning. The right way for a man who wishes to commit suicide would be the way to a precipice over which he desires to throw himself. But the same way is the wrong way for him, if he wishes to avoid the danger of falling. In this way we may speak of the right way of doing the most wicked things. One most eminent expounder of the Utilitarian theory has taken advantage of this common use of the words "good" and "bad," and of "right" and wrong," to represent utility and inutility to be the essential idea of all goodness and of all badness respectively.[3] Thus the unavoidable ambiguities of speech are employed to give a scientific aspect to the confounding and obliteration of the profoundest distinctions which exist in knowledge. By the double process of expelling from goodness the idea of virtue, and of inserting into utility the idea of beneficence, the fallacies of language become complete. Because subserviency to purpose of any kind is the meaning of "good," when applied equally to an instrument of torture and to an instrument for the relief of suffering, therefore, it is argued, the same meaning must be the essential one when we speak of a good man. And so indeed it may be, if we know or assume beforehand what the highest purpose is to which Man can be made subservient. There is a well-known Catechism of one of the Reformed churches which opens with the qnestion, "What is the chief end of Man?" The answer is perhaps one of the noblest in the whole compass of theology. "Man's chief end is to glorify God and to enjoy Him forever."[4] Given certain further beliefs as to the character of the Divine Being, and the methods of his Government, then indeed it would be true that this is a conception of the purpose of Man's existence which would erect mere serviceableness or utility into a perfect rule of conduct. Perhaps even a lower or less perfect conception of the great aim of Man's life would be almost enough. If virtue and beneficence are first assumed to be the highest purpose of his being, then subserviency to that purpose may be all that is meant by goodness. But, without this assumption as to the "chief end of Man," there would be no ethical meaning whatever in the phrase of "a good man." It might mean a good thief, or a good torturer, or a good murderer. Utility, that is to say, mere subserviency to any purpose, is undoubtedly a good thing in itself, and of this kind is the goodness of a machine which is invented for a bad or evil purpose. But this utility in the machine is, so far as the machine is concerned, destitute of any moral character whatever, and, so far as those who employ it are concerned, the utility is not virtuous, but, on the contrary, it is vicious. It is clear, therefore, that when the word "utility" is used as meaning moral or even physical good, and still more when it is identified with virtue, or when it is declared to be the standard of that which is right or virtuous in conduct, the word is used not in its own proper sense, but in a special or adventitious sense, in which it is confined to one special kind of usefulness, namely, that which conduces to good ends, and good aims, and good purposes. That is to say, the sense in which utility is spoken of as the test or standard of virtue is a sense which assumes that goodness and virtue are independently known, or, in other words, that they are determined and recognized by some other test and some other standard.

It is, however, clear that when by this other test and standard, whatever it may be, we have already felt or apprehended that it is right and virtuous to do good to others, then the usefulness of any action or of any course of conduct, in the production of such good, does become a real test and indication of that which we ought to do. It is a test or indication of the particular things which it is right to do, but not at all a test of the moral obligation which lies upon us to do them. This obligation must be assumed, and is assumed, in every argument on the moral utility of things. It is by confounding these two very distinct ideas that the Utilitarian theory of the ultimate basis of moral obligation has so long maintained a precarious existence, borrowing from the misuse of words a strength which is not its own. But the moment this distinction is clearly apprehended, then, although we set aside the bare idea of usefulness, apart from the good or bad purpose towards which that usefulness conduces, as affording any explanation whatever of the ultimate nature and source of duty, we may well, nevertheless, be ready to adopt all that the Utilitarian theory can show us of that inseparable unity which is established in the constitution of the world between the moral character and the ultimate results of conduct. As far as these results can be traced beforehand, and in proportion as they can be traced farther and farther in the light of expanding knowledge, they do indicate the path of duty. They do indicate the line of action which is obligatory on voluntary agents, to whom a very large amount of power is given in directing the course of things. Beyond all doubt there are a thousand acts and a thousand courses of conduct which are in accordance with the Moral Sense, because and only because of the known happiness of their effects. This is the fact, or rather the class of facts, which has in all ages recommended the Utilitarian theory of morals to so many powerful minds. For, indeed, if we understand by utility not the low or limited idea of mere usefulness for any purpose—not even the

[3] Herbert Spencer: "Data of Ethics," chap. iii.

[4] "The Shorter Catechism, presented by the Westminster Assembly of Divines to both Houses of Parliament, and by them approved."

mere idea of pleasure as an unquestionable good of its own kind, nor the mere idea of immediate profit or advantage—but the very different conception of the beneficence of ultimate results on the welfare of all men and of all creatures, then there may be, and probably there is, an universal and absolute coincidence between the things which it is wise and the things which it is right to do. Men may imagine, and they have imagined, that under this conception of utility they can devise a system of morality which is of such transcendental excellence that it is far too good for earth. Thus it has been laid down that evolution, in its most perfect conception, would be such that the development of every creature would be compatible with the equal development of every other. In such a system there would be no "struggle for existence—no harmful competition, no mutual devouring —no death."[5] The inspired imaginings of the Jewish prophets of some future time when the lion shall lie down with the lamb, and the ideas which have clustered round the Christian Heaven, are more probably the real origin of this conception than any theory of evolution founded on the facts and laws of Nature. But, for all practical purposes, such a system of ethics is as useless as the dreams of Plato's Republic or of More's Utopia. If, however, we have got from some independent source a right idea of that which will be most beneficent in its ultimate results, we may well be guided by this light in so far as we can see it. But inasmuch as these far-off results and tendencies of conduct cannot always be within sight, and are indeed very often wholly beyond the horizon visible to us, this admission, or rather this high doctrine that the right and the useful are always coincident, is a widely different doctrine from that which identifies the sense of obligation with the perception of utility. The mere perception that any act or course of conduct will certainly be beneficent in its results, would be of no avail without the separate feeling that it is right to strive for results which are beneficent.

And here it is well worthy of observation, that in direct proportion to the height and sublimity of the meaning artificially attached to the word "utility," it becomes less and less available as a test or as a rule of conduct. So long as the simple and natural meaning was put upon utility, and the good was identified with the pleasurable, the Utilitarian theory of morals did indicate at least some rule of life, however low that rule might be. But now that the apostles of that theory have been driven to put upon utility a transcendental meaning, and the pleasurable is interpreted to refer not merely to the immediate and visible effects of conduct on ourselves or others, but to its remotest effects upon all living beings, both now and for all future time, the Utilitarian theory in this very process of sublimation becomes lifted out of the sphere of human judgment. If it be true "that there can be no correct idea of a part without a correct idea of the correlative whole," and if human conduct in its tendencies and effects is only "a part of universal conduct,"[6]—that is to say, of the whole system of the universe in its past, its present, and its future—then, as this whole is beyond all our means of knowledge and comprehension, it follows that utility, in this sense, can be no guide to us. If indeed this system of the universe has over it or in it one Supreme Authority, and if we knew on that authority the things which do make, not only for our own everlasting peace, but for the perfect accomplishment of the highest purposes of creation to all living things, then indeed the rule of utility is resolved into the simple rule of obedience to legitimate Authority. And this is consistent with all we know of the Unity of Nature, and with all that we can conceive of the central and ultimate Authority on which its order rests. All intuitive perceptions come to us from that Authority. All the data of reason come to us from that Authority. All these in their own several spheres of operation may well guide us to what is right, and may give us also the conviction that what is right is also what is best, "at last, far off, at last to all."

Thus far a clear and consistent answer can be given to one of the greatest questions of ethical inquiry, namely, the nature of the relation between those elements in conduct which make it useful, and those elements in conduct which make it virtuous. The usefulness of conduct in promoting ends and purposes which are good is, in proportion to the nature and extent of that good, a test and an index of its virtue. But the usefulness of conduct in promoting ends and purposes which are not good is a mark and index, not of virtue, but of vice. It follows from this that utility in itself has no moral character whatever apart from the particular aim which it tends to accomplish, and that the moral goodness of that aim is presupposed when we speak or think of the utility of conduct as indicative of its virtue. But this character of goodness must be a matter of independent and instinctive recognition, because it is the one distinction between the kind of usefulness which is virtuous and the many kinds of usefulness which are vicious. Accordingly we find in the last resort that our recognition of goodness in the conduct of other men towards ourselves is inseparable from our own consciousness of the needs and wants of our own life, and of the tendency of that conduct to supply them. This estimate of goodness seated in the very nature of our bodies and of our minds, becomes necessarily, also, a standard of obligation as regards our conduct to others: for the unity of our nature with that of our kind and fellows is a fact seen and felt intuitively in the sound of every voice and in the glance of every eye around us.

But this great elementary truth of morals, that we ought to do to others as we know we should wish them to do to us, is not the only truth which is intuitively perceived by the Moral Sense. There is, at least, one other among the rudiments of duty which is quite as self-evident, quite as important, quite as far-reaching in its consequences, and quite as early recognized. Obedience to the will of legitimate Authority is necessarily the first of all motives with which the sense of obligation is inseparably associated; whilst its opposite, or rebellion against the commands of legitimate Authority, is the spirit and the motive upon which the Moral Sense pronounces its earliest sentence of disapproval and of condemnation. At first sight it may seem as if the legitimacy of any Authority is a previous question requiring itself to be determined by the Moral Sense, seeing that it is not until this character of legitimacy or rightfulness has been recognized as belonging to some particular Authority, that obedience to its commands comes in consequence to be recognized as wrong. A moment's consideration, however, will remind us that there is at least one Authority the rightfulness of which is not a question but a fact. All men are born of parents. All men, moreover, are born in a condition of utter helplessness and of absolute dependence. As a mattor of fact, therefore, and not at all as a matter of question or of doubt, our first conception of duty, or of moral obligation, is necessarily and universally attached to such acts as are in conformity with the injunctions of this last and most indisputable of all Authorities.

Standing, then, on this firm ground of universal and necessary experience, we are able to affirm with absolute conviction that our earliest conceptions of duty—our earliest exercises of the Moral Sense—are not determined by any considerations of utility, or by any conclusions of the judgment on the results or on the tendencies of conduct.

But the same reasoning, founded on the same principle of simply investigating and ascertaining facts, will carry us a great way farther on. As we grow up from infancy, we find that our parents are themselves also subject to Authority, owing and owning the duty of obedi-

Herbert Spencer: "Data of Ethics," chap. ii. pp. 18, 19.

Herbert Spencer: "Dara of Ethics," chap. i. pp. 1-6.

ence to other persons or to other powers. This higher Authority may be nothing but the rules and customs of a rude tribe; or it may be the will of an absolute sovereign; or it may be the accumulated and accepted traditions of a race; or it may be the laws of a great civilized community; or it may be the Authority, still higher, of that Power which is known or believed to be supreme in Nature. But in all and in each of these cases, the sense of obligation is inseparably attached to obedience to some Authority, the legitimacy or rightfulness of which is not itself a question but a fact.

It is true, indeed, that these rightful Authorities, which are enthroned in Nature, are fortified by power to enforce their commands, and to punish violations of the duty of obedienee. It is true, therefore, that from the first moments of our existence the sense of obligation is re-inforced by the fear of punishment. And yet we know, both as a matter of internal consciousness, and as a matter of familiar observation in others, that this sense of obligation is not only separable from the fear of punishment, but is even sharply contra-distinguished from it. Not only is the sense of obligation powerful in cases where the fear of punishment is impossible, but in direct proportion as the fear of punishment mixes or prevails, the moral character of an act otherwise good is diminished or destroyed. The fear of punishment and the hope of reward are, indeed, auxiliary forces which cannot be dispensed with in society. But we feel that complete goodness and perfect virtue would dispense with them altogether, or rather, perhaps, it would be more correct to say, that the hope of reward would be merged and lost as a separate motive in that highest condition of mind in which the performance of duty becomes its own reward, because of the satisfaction it gives to the Moral Sense, and because of the love borne to that Authority whom we feel it our duty to obey.

The place occupied by this instinctive sentiment in the equipment of our nature is as obvious as it is important. The helplessness of infancy and of childhood is not greater than would be the helplessness of the race if the disposition to accept and to obey Authority were wanting in us. It is implanted in our nature only because it is one of the first necessities of our life, and a fundamental condition of the development of our powers. All Nature breathes the spirit of authority, and is full of the exercise of command. "Thou shalt," or "Thou shalt not," are words continually on her lips, and all her injunctions and all her prohibitions are backed by the most tremendous sanctions. Moreover, the most tremendous of these sanctions are often those which are not audibly proclaimed, but those which come upon us most gradually, most imperceptibly, and after the longest lapse of time. Some of the most terrible diseases which afflict humanity are known to be the results of vice, and what has long been known of some of those diseases is more and more reasonably suspected of many others. The truth is, that we are born into a system of things in which every act carries with it, by indissoluble ties, a long train of consequences reaching to the most distant future, and which for the whole course of time affect our own condition, the condition of other men, and even the conditions of external nature. And yet we cannot see those consequences beyond the shortest way, and very often those which lie nearest are in the highest degree deceptive as an index to ultimate results. Neither pain nor pleasure can be accepted as a guide. With the lower animals, indeed, these, for the most part, tell the truth, the whole truth, and nothing but the truth. Appetite is all that the creature has, and in the gratification of it the highest law of the animal being is fulfilled. In Man, too, appetite has its own indispensable function to discharge. But it is a lower function, and amounts to nothing more than that of furnishing to Reason a few of the primary data on which it has to work—a few and a few only. Physical pain is indeed one of the threatenings of natural authority; and physical pleasures is one of its rewards. But neither the one nor the other forms more than a mere fraction of that awful and imperial code under which we live. It is the code of an everlasting Kingdom, and of a jurisprudence which endures throughout all generations. It is a code which continually imposes on Man the abandonment of pleasure, and the endurance of pain, whenever and wherever the higher purposes of its law demand of him the sacrifice. Nor has this spirit of Authority ever been without its witness in the human Spirit, or its response in the human Will. On the contrary, in all ages of the world, dark and distorted as have been his understandings of Authority, Man has been prone to acknowledge it, and to admit it as the basis of obligation and the rule of duty. This, at all events, is one side of his character, and it is universally recognized as the best.

There is no difficulty, then, in seeing the place which this instinct holds in the unity of Nature. It belongs to that class of gifts, universal in the world, which enable all living things to fulfill their part in the order of Nature, and to discharge the functions which belong to it. It is when we pass from a review of those instincts and powers with which Man has been endowed, to a review of their actual working and results, that we for the first time encounter facts which are wholly exceptional, and which it is, accordingly, most difficult to reconcile with the unities of Nature. This difficulty does not lie in the mere existence of a Being with powers which require for their perfection a long process of development. There is no singularity in this. On the contrary, it is according to the usual course and the universal analogy of Nature. Development in different forms, through a great variety of stages and at different rates of progress, is the most familiar of all facts in creation. In the case of some of the lower animals, and especially in the case of many among the lowest, the process of development is carried to an extent which may almost be said to make the work of creation visible. There are numberless creatures which pass through separate stages of existence having no likeness whatever to each other. In passing through these stages, the same organism differs from itself in form, in structure, in the food on which it subsists, and even in the very element in which it breathes and lives. Physiologists tell us that changes having a mysterious and obscure analogy with these pass over the embryo of all higher animals before their birth. But after birth the development of every individual among the higher orders of creation is limited to those changes which belong to growth, to maturity, and decay. Man shares in these changes, but in addition to those he undergoes a development which effects him not merely as an individual, but as a species and a race. This is purely a development of mind, of character, and of knowledge, giving by accumulation from generation to generation increased command over the resources of Nature, and a higher understanding of the enjoyments and of the aims of life.

It is true, indeed, that this is a kind of development which is itself exceptional—that is to say, it is a kind of development of which none of the lower animals are susceptible, and which therefore separates widely between them and Man. But although it is exceptional with reference to the lower orders of creation it is very important to observe that it constitutes no anomaly when it is regarded in connection with creation as a whole. On the contrary, it is the natural and necessary result of the gift of reason and of all those mental powers which are its servants or allies. But all Nature is full of these—so full, that every little bit and fragment of its vast domain overflows with matter of inexhaustible interest to that one only Being who has the impulse of inquiry and the desire to know. This power or capacity in every department of Nature of fixing the attention and of engrossing the interest of Man,

depends on the close correspondence between his own faculties and those which are reflected in creation, and on his power of recognizing that correspondence as the highest result of investigation. The lower animals do reasonable things without the gift of reason, and things, as we have seen, often involving a very distant foresight, without having themselves any knowledge of the future. They work for that which is to be, without seeing or feeling anything beyond that which is. They enjoy, but they cannot understand. Reason is, as it were, brooding over them and working through them, whilst at the same time it is wanting in them. Between the faculties they possess, therefore, and the governing principles of the system in which they live and under which they serve, there is, as it were, a vacant space. It is no anomaly that this space should be occupied by a Being with higher powers. On the contrary, it would be the greatest of all anomalies if it were really vacant. It would be strange indeed if there were no link connecting, more closely than any of the lower animals can connect, the Mind that is in creation with the mind that is in the creature. This is the place occupied by Man's Reason—Reason not outside of, but in the creature—working not only through him, but also in him—Reason conscious of itself, and conscious of the relation in which it stands to that measureless Intelligence of which the Universe is full. In occupying this place, Man fills up, in some measure at least, what would otherwise be wanting to the continuity of things; and in proportion as he is capable of development—in proportion as his faculties are expanded—he does fill up this place more and more.

There is nothing, then, really anomalous or at variance with the unity of Nature, either in the special elevation of the powers which belong to Man, or in the fact that they start from small beginnings and are capable of being developed to an extent which, though certainly not infinite is at least indefinite. That which is rarely exceptional, and indeed absolutely singular in Man, is the persistent tendency of his development to take a wrong direction. In all other creatures it is a process which follows a certain and determined law, going straight to a definite, consistent, and intelligible end. In Man alone it is a process which is prone to take a perverted course, tending not merely to arrest his progress, but to lead him back along descending paths to results of utter degradation and decay. I am not now affirming that this has been the actual course of Man as a species or as a race when that course is considered as a whole. But that it is often the course of individual men, and that it has been the course of particular races and generations of men in the history of the world, is a fact which cannot be denied. The general law may be a law of progress; but it is certain that this law is liable not only to arrest but to reversal. In truth it is never allowed to operate unopposed, or without heavy deductions from its work. For there is another law ever present, and ever working in the reverse direction. Running alongside, as it were, of the tendency to progress, there is the other tendency to retrogression. Between these two there is a war which never ceases,—sometimes the one, sometimes the other, seeming to prevail. And even when the better and higher tendency is in the ascendant, its victory is qualified and abated by its great opponent. For just as in physics the joint operation of two forces upon any moving body results in a departure from the course it would have taken if it had been subject to one alone, so in the moral world almost every step in the progress of mankind deviates more or less from the right direction. And every such deviation must and does increase, until much that had been gained is again lost, in new developments of corruption and of vice. The recognition of this fact does not depend on any particular theory as to the nature or origin of moral distinctions. It is equally clear, whether we judge according to the crudest standard of the Utilitarian scheme, or according to the higher estimates of an Independent Morality. Viewed under either system, the course of development in Man cannot be reconciled with the ordinary course of Nature, or with the general law under which all other creatures fulfill the conditions of their being.

It is no mere failure to realize aspirations which are vague and imaginary that constitutes this exceptional element in the history and in the actual condition of mankind. That which constitutes the terrible anomaly of his case admits of perfectly clear and specific definition. Man has been and still is a constant prey to appetites which are morbid—to opinions which are irrational, to imaginations which are horrible, and to practices which are destructive. The prevalence and the power of these in a great variety of forms and of degrees is a fact with which we are familiar—so familiar, indeed, that we fail to be duly impressed with the strangeness and the mystery which really belong to it. All savage races are bowed and bent under the yoke of their own perverted instincts—instincts which generally in their root and origin have an obvious utility, but which in their actual development are the source of miseries without number and without end. Some of the most horrible perversions which are prevalent among savages have no counterpart among any other created beings, and when judged by the barest standard of utility, place Man immeasurably below the level of the beasts. We are accustomed to say of many of the habits of savage life that they are "brutal." But this is entirely to misrepresent the place which they really occupy in the system of Nature. None of the brutes have any such perverted dispositions; none of them are ever subject to the destructive operation of such habits as are common among men. And this contrast is all the more remarkable when we consider that the very worst of these habits affect conditions of life which the lower animals share with us, and in which any departure from those natural laws which they universally obey, must necessarily produce, and do actually produce, consequences so destructive as to endanger the very existence of the race. Such are all those conditions of life affecting the relation of the sexes which are common to all creatures, and in which Man alone exhibits the widest and most hopeless divergence from the order of Nature.

It fell in the way of Malthus in his celebrated work on Population to search in the accounts of travelers for those causes which operate, in different countries of the world, to check the progress, and to limit the numbers of Mankind. Foremost among these is vice, and foremost among the vices is that most unnatural one, of the cruel treatment of women. "In every part of the world," says Malthus, "one of the most general characteristics of the savage is to despise and degrade the female sex. Among most of the tribes in America, their condition is so peculiarly grievous, that servitude is a name too mild to describe their wretched state. A wife is no better than a beast of burden. While the man passes his days in idleness or amusement, the woman is condemned to incessant toil. Tasks are imposed upon her without mercy, and services are received without complacence or gratitude, There are some districts in America where this state of degradation has been so severely felt that mothers have destroyed their female infants, to deliver them at once from a life in which they were doomed to such a miserable slavery."[7] It is impossible to find for this most vicious tendency any place among the unities of Nature. There is nothing like it among the beasts. With them the equality of the sexes, as regards all the enjoyments as well as all the work of life, is the universal rule. And among those of them in which social instincts have been specially implanted, and whose system of polity are like the most civilized polities of men, the females of the race are treated with a strange mixture of love, of loyalty, and of devotion. If, indeed, we consider

the necessary and inevitable results of the habit prevalent among savage men to maltreat and dagrade their women,—its effects upon the constitution, and character, and endurance of children, we cannot fail to see how grossly unnatural it is, how it must tend to the greater and greater degradation of the race, and how recovery from this downward path must become more and more difficult or impossible. But vicious, destructive, unnatural as this habit is, it is not the only one or the worst of similar character which prevail among savage men. A horrid catalogue comes to our remembrance when we think of them—polyandry, infanticide, cannibalism, deliberate cruelty, systematic slaughter connected with warlike passions or with religious customs. Nor are these vices, or the evils resulting from them, peculiar to the savage state. Some of them, indeed, more or less changed and modified in form, attain a rank luxuriance in civilized communities, corrupt the very bones and marrow of society, and have brought powerful nations to decay and death.

It is, indeed, impossible to look abroad either upon the past history or the existing condition of mankind, whether savage or civilized, without seeing that it presents phenomena which are strange and monstrous—incapable of being reduced within the harmony of things or reconciled with the unity of Nature. The contrasts which it presents to the general laws and course of Nature cannot be stated too broadly. There is nothing like it in the world. It is an element of confusion amidst universal order. Powers exceptionally high spending themselves in activities exceptionally base; the desire and the faculty of acquiring knowledge coupled with the desire and the faculty of turning it to the worst account; instincts immeasurably superior to those of other creatures, along side of conduct and of habits very much below the level of the beasts—such are the combinations with which we have to deal as unquestionable facts when we contemplate the actual condition of Mankind. And they are combinations in the highest degree unnatural; there is nothing to account for, or to explain them in any apparent natural necessity.

The question then arises, as one of the greatest of all mysteries—how it is and why it is that the higher gifts of Man's nature should not have been associated with corresponding dispositions to lead as straight and as unerringly to the crown and consummation of his course, as the dispositions of other creatures do lead them to the perfect development of their powers and the perfect discharge of their functions in the economy of Nature?

It is as if weapons had been placed in the hands of Man which he has not the strength, nor the knowledge, nor the rectitude of will to wield aright. It is in this contrast that he stands alone. In the light of this contrast we see that the corruption of human nature is not a mere dogma of theology, but a fact of science. The nature of man is seen to be corrupt not merely as compared with some imaginary standard which is supposed to have existed at some former time, but as compared with a standard which prevails in every other department of Nature at the present day. We see, too, that the analogies of creation are adverse to the supposition that this condition of things was original. It looks as if something exceptional must have happened. The rule throughout all the rest of Nature is, that every creature does handle the gifts which have been given to it with a skill as wonderful as it is complete, for the highest purposes of its being, and for the fulfillment of its part in the unity of creation. In Man alone we have a being in whom his adjustment is imperfect—in whom this faculty is so defective as often to miss its aim. Instead of unity of law with certainty and harmony of result, we have antagonism of laws, with results, at the best, of much shortcoming and often of hopeless failure. And the anomaly is all the greater when we consider that this failure affects chiefly that portion of Man's nature which has the direction of the rest—on which the whole result depends, as regards his conduct, his happiness, and his destiny. The general fact is this:—First, that Man is prone to set up and to invent standards of obligations which are low, false, mischievous, and even ruinous; and secondly, that when he has become possessed of standards of obligation which are high, and true, beneficient, he is prone first, to fall short in the observance of the , and next, to suffer them, through various processes of decay, to be obscured and lost.

ASTRONOMY.

THE LICK OBSERVATORY.

Work upon Mount Hamilton, the site of the new Lick Observatory, has been pushed forward as rapidly as could be expected, and it is probable that the building will be sufficiently finished to receive a portion of the instruments in the fall of this year. For instrumental equipment, a 12-inch Clark glass and tube, made for Dr. Draper, has been bought, and will be fitted to an equatorial mounting. A 4-inch transit, made on the same patterns as the 4-inch meridian circle of Princeton College, with a few changes introduced by Professors Newcomb and Holden, has been ordered from Fauth & Co., of Washington. It will be sent to California in October, and will probably be mounted by Prof. Holden, and used by him in connection with the 12-inch equatorial, to observe the transit of Mercury on November 7, 1881. A Repsolds meridian circle of six inches aperture will soon be ordered, as well as a small vertical circle. Alvan Clark & Sons, of Cambridge, have received the contract to make a glass three feet in diameter, at a cost of $50,000. The equatorial mounting for this immense objective (44 per cent. more powerful than that ordered for the Russian Government, with aperture of 30 inches, and 100 per cent. more powerful than the great Washington refractor) is not yet provided for. Proposals will be obtained from the principal instrument makers of Europe and this country, and the mechanical part will probably cost as much as the optical.

General plans for the buildings were prepared by Professors Newcomb and Holden, in August, 1880, and will govern the more detailed plans which are to be prepared by the architects. A dome for the 12-inch equatorial is already in process of construction.

The work done upon Mt. Hamilton by Mr. Burnham in the summer of 1879 shows how well suited the high situation is for astronomical observations, and much will be expected from an observatory so well provided with powerful instruments.

"THE 'ASTRONOMISCHE NACHRICHTEN.'—Contrary to what has been lately stated, it appears that this periodical will still be edited by Dr. C. F. W. Peters, who has for some time conducted it, and we are informed there is a probability that Prof. Kruger may set afloat a new astronomical journal under his own management."—*Nature.*

SITE FOR THE NEW NAVAL OBSERVATORY.—The Commission appointed by Congress to select a site for the proposed new Naval Observatory has purchased the Barbour estate, in Georgetown, at a cost of $63,000. A detailed description of the location will shortly appear.

W. C. W.

WASHINGTON, *March* 10, 1881.

We notice, in the last number of the *Chemical News*, that Mr. M. Benjamin, to whom we are indebted for notices of the American Chemical Society, was elected a Fellow of the Chemical Society, London.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

MICROSCOPY.

To the Editor of "SCIENCE:"

Dear Sir:—I am authorized by the President of the American Society of Microscopists to announce to its members, and to all others who may be interested, that the Executive Committee have decided, by an almost unanimous vote, to accept the invitation received from the Tyndall Association of Natural Science, of Columbus, Ohio, and to call the next meeting of the Society at that place on Tuesday, August 9, 1881, (the week previous to the meeting of the American Association for the Advancement of Science, at Cincinnati).

Permit me to add a word upon another matter. The proceedings of the American Society, which should have appeared two months ago, have been unavoidably delayed by circumstances which I shall explain to members at the time of issuing the volume. The latter is now in the press, and will be sent out before the end of the month. ALBERT H. TUTTLE, Sec'y.

COLUMBUS, Ohio, *March* 1, 1881.

BOOKS RECEIVED.

BACTERIA. BY DR. ANTOINE MAGNIN, General Secretary of the Botanical Society of Lyons, &c., &c. Translated by George M. Sternberg, M. D., U. S. A. Boston—Little, Brown, & Company. 1880. Price $2.50.

The present translation of Dr. Magnin's work by Dr. Sternberg will be welcome in all English speaking countries, and we trust its circulation may remove much of the ignorance which exists on this subject, among a large class of professional men, who would perhaps be ashamed to confess their want of knowledge.

Among physicians Dr. Magnin's work on the Bacteria should find a wide range of readers; to many it will read like a revelation, and may be the means of developing original ideas, which may give them a fresh impulse in their profession.

It has been a hard struggle with Nature, accompanied by the greatest difficulties, to solve the many problems involved in the phenomena attributed to Bacteria. One hundred and fifty years have passed since Leeuwenhoek, the Father of Microscopy, wrote the first paper on the subject, and Dr. Magnin occupies thirty-one pages of his work in recording a Bibliography of the works of those who have since contributed papers.

By the aid of this large amount of literature treating on Bacteria, supported by his own experience, Dr. Magnin has produced a work, a careful perusal of which will greatly reduce the difficulties of further investigations in solving the many problems still waiting for solution.

A full classification of the genera and species of Bacteria is given, with sufficient descriptions of their forms and characteristics to make their identification an easy task, and although this classification is merely provisional, its practical utility for student's work is not impaired.

We observe ten full-sized plates of engravings, each having from four to twenty-two illustrations of Bacterian forms.

No person possessing a Microscope should be without this book, and it should be closely studied by every physician.

The temptation is great to enter into a description of the varied contents of the work, but the subject is too intricate to be disposed of in a short paragraph and must be reserved for future treatment.

Bacteria are of all beings the most widely diffused; we meet with them everywhere, in the air, in the water, upon the surface of solid bodies, in the interior of plants and animals. They are the cause of disease, and the great agent in putrefaction, and yet the continuance of life on this globe would not be possible without them; they are so minute that some defy measurement with the highest powers of the microscope, but they become a mighty factor in the economy of creation by reason of their wonderful powers of reproduction, for in twenty-four hours the product of a single bacterium by division amounts to sixteen millions of individuals, and at this rate the ocean itself—calculating it equal to two-thirds of the terrestial surface, with a mean depth of one mile, equalling 920,000,000 cubic miles—would be filled with Bacteria in five days from a single germ, supposing the multiplication to be continued with the same conditions.

Fortunately researches of microscopists have brought to light facts regarding these organisms which enable man to control their prodigious reproductive powers, and our knowledge relating to Bacteria will probably at length be acknowledged as one of the greatest victories of modern science.

NOTES.

A PROCESS FOR THE TOTAL DESTRUCTION OF THE ORGANIC MATTERS IN THE DETECTION OF POISONOUS MINERAL SUBSTANCES.—From 100 to 500 grms. of the suspected matter are mixed in a large porcelain capsule with one-fourth its weight of the acid sulphate of potassa, and then with its own weight of fuming nitric acid. The action is very violent at first, and requires afterwards the aid of a slight heat. Here it is proper to stop if it is merely needful to search for arsenic or antimony. A large excess of pure concentrated sulphuric acid (1.845 sp. gr.) is then added, and the mixture is heated to near the boiling point of the acid. More acid is added from time to time till the mixture becomes pale and limpid. To complete the destruction of the last traces of organic matter it is well to let the liquid cool, add a few crystals of pure potassium nitrate, and heat again till abundant white vapors of sulphuric acid are evolved. The saline mass when cold is dissolved in boiling water, made up to 1 litre, and without previous filtration it is submitted to electrolysis by means of 4 Bunsen elements or a Clamond gas-battery. The negative platinum electrode becomes covered with a grey, blackish, or metallic coating. The action should be prolonged for twenty-four hours. If mercury is suspected a plate of gold should be used at the negative pole instead of platinum. If arsenic or antimony is sought for before the addition of the sulphuric acid, the carbonacious mass is cooled, powdered, and treated with boiling water. The solution thus obtained is examined as proposed by Dr. A. Gautier. (*Comptes Rendus*, August, 1875).—A. G. POUCHET.

DETERMINATION OF CARBONIC ACID IN THE AIR.—The authors, after referring to the discordant results obtained in the determination of atmospheric carbonic acid, describe their method. The carbonic acid is fixed by an absorbent body, from which it is afterwards set at liberty and measured by volume. As an absorbent they use pumice stone saturated with solution of potassa, and contained in a tube drawn out at both ends. The tubes are washed with sulphuric acid, filled with small fragments of pumice, calcined with sulphuric acid, and introduced while hot. The pumice is saturated with a given volume of potassa lye, operating in air deprived of carbonic acid. The lye is prepared by dissolving 1 kilo. potassa in 1.400 litres of water, and adding 200 grms. hydrated baryta to remove sulphates and carbonates. The tubes, prepared beforehand and sealed, are opened at the place of operation, and sealed again after 200 litres of air have been passed through.—A. MUNTZ and E. AUBIN.

RESIDUES FROM THE MANUFACTURE OF OILS FROM SCHISTS. The solid residues serve for the manufacture of alum, and may become an important source of lithia. The acid tarry matters contain sulphates of the bases of the pyridic series, especially of corindine, rubidine, and viridine. Aniline is not sensibly present. The insoluble portions and the alkaline tars contain peculiar phenols, thymols β and γ. There is no ordinary phenic acid, and very little thymol α.—GASTON BONG.

SWINE PLAGUE.

The present discussion on the infectious disease existing among hogs in the United States, known as the "*Swine Plague*" will, we trust, be productive of some good in giving publicity to certain facts relating to this subject, which should be known and understood by all interested in the sale or consumption of pork.

It appears that a report was sent from the British Consulate at Philadelphia, to England, stating that 700,000 hogs had died of Swine Plague during the year 1880, in one of the Western States.

Those interested in the export trade have contested this statement, and with the very laudable motive of protecting an important American home interest, have endeavored to show that the action of the Consul was founded on erroneous information, and one journal in New York even accuses the British officials of "plotting a senseless scare."

It appears to be now officially admitted that 300,000 hogs died of this disease in one State alone in 1880; and, therefore, the real question now at issue, is not whether the disease exists, but merely how many hundred thousand hogs die in consequence of it annually in each State.

Without going outside of United States official documents the real facts of the case may be stated as follows:

The Swine Plague came into notice about 25 years ago, and on account of its excessive infectious nature, it steadily increased annually until the year 1878, when the Commissioner of Agriculture announced an annual death-rate of hogs for the United States, amounting to a money value of $20,000,000; as the victims are said to be chiefly among the smaller and leaner animals, probably $2 per head would be a fair average of value; in that case the number of deaths among hogs by the Swine Plague, actually taken by census, would be 10,000,000 for that year.

As this disease is no sudden epidemic, but has been progressing for a quarter of a century, it is not likely that, in the two years and a half which have passed since this report was made to the United States Government, the disease has much abated. The disease is at this date officially admitted to be raging, and the mere question of its destructive effects, is only one of degree.

Under these circumstances it would appear unjust to accuse foreign consuls of partial conduct in reporting these facts, and it is equally futile to attempt to suppress them.

The behavior of the New York Produce Exchange in this matter reminds us of the action of the ostrich when it buries its head in the sand at the approach of danger. We have one word of advice to those who would preserve the United States export trade in pork, and that is to admit the existence of Swine Plague, and the increasing contamination of pork by trichinæ. This done, it is not difficult to organize such a system of inspection as will satisfy foreign governments that the shipments of pork from this country are such as can be received with safety. At the date of our writing, a cable dispatch announces that the Austrian Government has interdicted the importation of American pork in any form, and unless our suggestion is accepted without delay, other foreign States will probably follow the example of Austria on this question.

Major J. W. Powell succeeds Clarence King as Director of the United States Geological Survey. This appointment appears to have given general satisfaction, and we consider it a fortunate circumstance that a gentleman of such high professional attainments has accepted this important position.

ACADEMY OF NATURAL SCIENCES OF PHILADELPHIA.

A course of practical instruction in Invertebrate Paleontology, to be given under the auspices of the Academy of Natural Sciences of Philadelphia, was inaugurated by Professor Angelo Heilprin, on Tuesday, March 8th, 1881, at 8 P. M., in the Hall of the Academy.

The lectures, twenty-five in number, will be continued on the successive Fridays and Tuesdays of each week, from 4 to 5 o'clock, P. M.

The plan of instruction will embrace the examination of the life-histories of the various geological formations, the discussion of the biological relations of past organic forms, and the practical determination of these forms for the purposes of paleontological inquiry. The demonstrations will be of an essentially practical nature, and will be based upon a careful study of the resources of the Academy's collections.

A course of practical instruction in Mineralogy was also inaugurated by Professor Henry Carvill Lewis, at the Academy of Natural Sciences of Philadelphia, on Tuesday, March 15th, at 8 P. M. The lectures will be continued on successive Mondays and Thursdays at 4 P. M., beginning March 21st.

The course will consist of ten lectures, and will be in great part practical, and confined to Determinative Mineralogy. Blowpipe analysis, and the application of simple chemical tests to the determination of minerals, will be especially dwelt upon. Students will be expected to devote at least half the time to the performance of practical work in this department.

The course will also embrace a reference to Physical and Crystallographic Mineralogy, and to Mineralogical classification.

Application for admission to the above courses may be made to Henry McCook, Chairman of the Committee on Instruction and Lectures.

A PARTIAL REVISION OF ANATOMICAL NOMENCLATURE, WITH ESPECIAL REFERENCE TO THAT OF THE BRAIN.*

By Burt G. Wilder, M. D., Professor of Comparative Anatomy, etc., in Cornell University, and of Physiology in the Medical School of Maine.

I.

INTRODUCTORY.

During the preparation of a paper "On the Gross Anatomy of the Brain of the Domestic Cat (*Felis domestica*)," I have been led to believe that some advantage may be gained by certain modifications of the current anatomical nomenclature. The present article contains suggestions, chiefly of a practical nature, which I wish to submit to other anatomists in the hope that, even if the changes here indicated do not meet their approval, they will be induced to take the general subject into consideration.

That the nomenclature of a science is worthy of attention is indicated by the care bestowed upon the language of modern chemistry and mathematics, and by the following expressions of opinion:

"Everything in science ought to be real, ingenuous and open; every expression that indicates duplicity, or equivocation, reservation, wavering or inconsistency, is a reproach to it."—Barclay, A., 89 †

"Questions of definition are of the very highest importance in philosophy, and they need to be watched accordingly." Duke of Argyll, 1.

"In all sciences, nomenclature is an object of importance; and each term should convey to the student a definite meaning." Dunglison, A, Preface.

"There is a necessity for perfect definiteness of language in all truly scientific work." P. G. Tait, 1.

"Technical terms are the tools of thought." ‡

"Only an inferior hand persists in toiling with a clumsy instrument, when a better one lies within his reach. . . . . . A single substantive term is a better instrument of thought than a paraphrase." Owen, A, I, Preface, pp. xii, xiv.

"As morphology deals with forms and relations of position, it demands a careful selection of terms and a methodical nomenclature." Goodsir, A, II, 83.

These remarks apply to the general subject of anatomical nomenclature. But the terms employed by anatomists form two divisions: those which indicate the *position* or *direction* of organs, and those by which the organs themselves are designated. Since, also, writers have usually treated of them separately, it will be convenient here to consider anatomical *toponomy* and *organonomy* under distinct headings.

TERMS OF POSITION AND DIRECTION—TOPONOMY.

Dr. Barclay's volume had especial reference to this division of the subject, and its key-note is struck in the following paragraph (A, 5):

"The vague ambiguity of such terms as superior, inferior, anterior, posterior, &c., must have been felt and acknowledged by every person the least versant with anatomical description."

Dunglison admits (A, 61) that "Great confusion has prevailed with anatomists in the use of the terms before, behind, &c." Dr. Spitzka has forcibly stated (1, 75, note 1) the objections to the use of anterior, &c., and their unsuitability is tacitly conceded in the employment of other terms by several writers who do not explicitly condemn the current toponomy: Gegenbaur (A, 491), Mivart (A, 69), Cleland (1, 170), Rolleston (B, 33, note), &c.

Finally, the need of a radical change of base has been proclaimed in one of the very strongholds of anthropotomy:

"Now that the more extended study of comparative anatomy and embryonic development is largely applied to the elucidation of the human structure, it is very desirable that descriptive terms should be sought which may, without ambiguity, indicate position and relation in the organism at once in man and animals. Such terms as cephalic and caudal, dorsal and ventral, &c., are of this kind, and ought, whenever this may be done consistently with sufficient clearness of description, to take the place of those which are only applicable to the peculiar attitude of the human body."—Quain, A, I, 6.

This is certainly explicit as to the principle involved, and it is to be hoped that later editions of this standard Human Anatomy may display its practical application to the body of the work.

How slender is the justification for retaining a toponomical vocabulary based upon the relations of organisms to the surface of the earth, appears more fully when we reflect that the assumed standard, for the higher vertebrates at least, is man in his natural erect attitude; yet that both man and animals are more often examined and compared when lying upon the *back*, this being an attitude truly characteristic of only that infrequent "subject," the sloth.

As a single illustration of the logical inconsistencies into which we are led by the use of the current toponomy, let us take the series of possible designations of the direction of some vertebral spinous process which projects toward the skin of the back at, or approximately at, a right angle with the myelon. With man the direction in which it points is *posterior*, but with a cat it is *superior*, while with an ape or a bird it is somewhere between the two; with all four, when on the dissecting table, it would be usually *inferior*. Finally, with a flounder the corresponding direction would be *horizontal* or *sidewise*.

In short, to designate the locations of organs by the relation of animals to the surface of the earth, which relation differs in nearly allied forms, and varies with the same individual according to circumstances, is as far from philosophical as it would be to define the place of a house or a tree by reference to the planet Jupiter, or to assume that mankind naturally face the rising sun, and hence to designate our right and left as the south and north sides of the body.

Some practical points respecting this division of the subject will be presented farther on.

DESIGNATION OF ORGANS,—ORGANONOMY.

There are probably few investigators or teachers of comparative anatomy who have not been impressed, in some degree, with the desirability of some modification of the prevailing nomenclature of organs,—the "bizarre nomenclature of anthropotomy," (Owen, A, II, 143)—based as it is upon the peculiar features of the human body, which has been fitly characterized, from a morphological point of view, as "not a model, but a monstrosity."

This impression may give rise to special papers, like those of Owen, (166), Maclise (1), and Pye-Smith (1, 16), or simply to more or less extended remarks upon the subject, with or without the use or presentation of new terms.

* This article is based upon two communications: the one, "A Partial Revision of the Nomenclature of the Brain," was read at the Boston meeting of the American Association for the Advancement of Science, August 28, 1880, and was reported, in part, in the *Boston Daily Advertiser*, of August 30, and in the New York Medical Record for September 18th, 1880; the other, "On some Points of Anatomical Nomenclature," was read at a meeting of the Cornell Philosophical Society, Ithaca, N. Y., January 15, 1881.

† In the List of Works and Papers at the end of this article, the names of the *authors* are placed in *alphabetical order*. The titles of *separate works* are designated by *letters*, and their order has no significance. The titles of *papers* are *numbered*. In the case of papers published between 1800 and 1873 the numbers correspond to those in the chronological "Catalogue of Scientific Papers published by the Royal Society of London." In other cases the numbers are only provisional, and are printed in italics.

The references are made as follows: the name of the author is given first, unless the author has been indicated already; then follows the letter or the number by which the title of the work or paper is designated upon the list; if a Roman numeral is given it denotes the number of the volume; and the last number is that of the page. This system of references was followed by me first in 1872, in the paper entitled Intermembral Homologies (10), and has been since adopted by others.

‡ I have mislaid the reference to the source of this aphorism. Perhaps some of my readers can supply it.

In the Preface to his "Anatomie du Chat" (A, pp. xiv—xvii), Straus-Durckheim devotes several pages to a discussion of anatomical nomenclature, and the body of the work contains many original names. Professor H. S. Williams calls attention (A, Preface), to the "crying need of a standard and uniform nomenclature of comparative anatomy."

In the preface to their recent account of the morphology of the skull (A), Parker and Bettany say: "It has been attempted to narrate the facts by means of a consistent terminology, amplifying what Prof. Huxley has so admirably developed." Several of Huxley's papers (as 70), contain new terms, most of which have been generally accepted, and in a greater or less degree the same is true of the elder Agassiz (A), Gegenbaur (59), Hæckel (A), Marsh (1), and others.

That my own consideration of the subject is not wholly of recent date may be seen from the papers numbered 10 and 2.

SCOPE AND METHODS OF THIS REVISION.

Most of the toponomical terms here discussed have a general application. But a revision of the organonomy of the entire body would extend this article beyond desirable limits.

As stated by Pye-Smith (1, 162), "the nomenclature of the brain stands more in need of revision than that of any other part," and on the present occasion I will simply endeavor to remove, in some degree, the deficiency implied in the following words of the French editors of "Huguenin" (A, Preface):

"That which is demanded of anatomy is an exact nomenclature and determination of the parts of the brain in their relative positions and contiguity, and if possible in their continuity."

Doubtless, for the entire comprehension of its functions, and even for the final determination of some of its homologies, the vertebrate brain should be fully understood in respect to the disposition of its cellular and fibrous elements,—that which the writers just mentioned term its *continuity*. But whoever is at all familiar with the literature of encephalic histology, or who has undertaken for himself the exhaustive study of even a very limited part of the brain will, if of sincere mind, admit the present impossibility of fairly discussing the microscopical terminology of the organ within the limits of a single article.

With the gross anatomy of the brain, the case is somewhat different. In the first place, some knowledge of it is requisite as a foundation for the histological enquiry, as well as for general work in human or comparative anatomy, physiology, and pathology. Secondly, the parts which are distinguishable by the naked eye are comparatively few, and while the numerous errors which may be found in even standard works sufficiently attest the difficulties of encephalotomy, its methods are comparatively simple. It is to be hoped, however, that the microscopical terminology and synonymy of the brain may shortly find due treatment.

A recent paper is entitled by its authors: "A *Reformed* System of Terminology, etc." Now the word *reform* is generally associated with questions of ethical improvement; whereas terminological reforms involve no other principle than that of expediency, taking into the account, however, the future as well as the present and the past. Such moral truisms as "do right because it is right" have no counterparts in considerations of scientific nomenclature, and he who, affected by the *cacoethes reformandi*, insists upon reform for the sake of an ideal perfection, is apt to appear as nothing better than a troublesome and useless pedant.

In the place, then, of what otherwise might be styled the principles of terminological reform, I will enumerate briefly the objects of the present revision, the considerations upon which it is based, and the methods which have been pursued :—

To facilitate the acquisition and communication of accurate anatomical knowledge, by rendering the vocabulary equally applicable to all vertebrates, and equally intelligible to all nations.

That the test of the accuracy and completeness of a description is, not that it may assist, but that it cannot mislead.

To include in this vocabulary, so far as practicable, only such terms as are brief, simple, significant, of classical origin, and capable of inflection.

To propose as few changes as possible, and to introduce new names only for parts apparently unknown or unnamed before (*e. g., crista fornicis*), or in the place of semi-descriptive appellations undesirably long or incapable of inflection, as *e.g., cimbia* for *tractus transversus pedunculi*, *porta* for *foramen Monroi*.

To consider *brevity* as an especially desirable characteristic of such names as are most frequently employed.

When a part is known by a descriptive phrase, to select therefrom some characteristic word as the technical designation; *e. g., iter* (*a tertio ad ventriculum quartum*).

When two or more parts are similar, or have similar relations, to distinguish them by joining to some common title already in use, prefixes indicative of their relative positions; *e.g., postgeniculatum, prægeniculatum*.

To shorten the names of several parts by omitting the word *corpus*, and using the neuter adjective as a substantive.

To keep modern usage, and the rules of classical etymology constantly in mind, but not to be hindered thereby from the employment or even the formation of terms which are eminently desirable from the practical standpoint.

To discard terms which indicate *size*, those which refer to the *natural attitude* of man or animals, most *vernacular* names, and all names of the reproductive organs which have been applied needlessly to other parts of the body.

With regard to the point last-named, while it may perhaps be urged in extenuation that the *patres anatomici* entertained a notion as to the representation of the entire organism in the brain, some of their words certainly indicate an entire freedom from apprehension that the mysteries of encephalic anatomy ever would be discussed by ordinary mortals, much less by women, or under circumstances requiring propriety of speech.

As has been stated, and as will be exemplified in the vocabulary, I have placed great stress upon *brevity* as a desirable characteristic of anatomical terms. So long as the study of anatomy was nearly confined to members of the medical profession, they being comparatively few in number, and, by ancient tradition at least, not wholly averse to clothing their discourse in a sesquipedalian garb impenetrable to the vulgar eye, it mattered little whether the statement of a given fact or idea required one minute or five. But now, thanks to the popular writings of Agassiz, Dana, Gray, Darwin, Hæckel, Huxley, Owen and others, in so far especially as they have aroused a personal interest in the problems of evolution, natural history instruction is given systematically in all schools and colleges, and the time seems to have come when, in the words of the naturalist first-named, "Scientific truth must cease to be the property of the few; it must be woven into the common life of the world." It is probable, indeed, that those who employ anatomical language to a greater or less extent at the present day are at least one hundred times as numerous as when Dr. Barclay's praiseworthy effort at reform was received with indifference or opposition.

It may be asked: In the face of this rapid popularization of anatomical knowledge is it worth while to introduce, or even to retain, any purely technical terms?

Apparently some German scientists have determined upon a negative reply to this inquiry, and their papers, even those of strictly scientific nature, teem with vernacular words, and with compounds thereof fearfully and wonderfully made.

If this kind of verbifaction be tolerable under any circumstances, it certainly would be justified by the extent and importance of the contributions to knowledge which appear first in the German scientific periodicals.

Upon this point, however, I can do no better than to quote the very recent judgment of one who is at the same time an investigator, a promoter of "the diffusion of knowledge," and an admirer of the methods and results of German science:

"Every art is full of conceptions which are peculiar to itself; and, as the use of language is to convey our conceptions to one another, language must supply signs for those conceptions. Either existing signs may be combined in loose and cumbrous paraphrases, or new signs, having a well-understood and definite signification, may be invented. Science is cosmopolitan, and the difficulties of the study of zoology would be prodigiously increased if zoologists of different nationalities used different technical terms for the same thing. They need a universal language; and it has been found convenient that the language shall be Latin in form, and Latin or Greek in derivation."—Huxley, C, 14.

Unless it can be shown that there is an essential distinction between the methods of designating entire organisms, and the parts thereof, the foregoing passages should silence the objections of those who would have us retain a vocabulary as vague as was that of chemistry in the days of lime, vitriol and copperas—a vocabulary which combines the ponderous stiffness of the cloister with the puerile vagueness of the nursery.

Tuberculum bigeminum anterius must give way to *lobi optici*, or some even shorter term; while *trachea* must take the place of *windpipe, weasand, luft-rohre* and *conduit ærien*. Life is too short to spend in digging for truth with a long-handled shovel when a trowel will serve the purpose; nor is it becoming that any nation, however wise and great, should ask all the rest to take their intellectual food with chop-sticks of its peculiar pattern.

That there is no inherent obstacle to the employment of technical terms of classical derivation is shown by the readiness with which such words as *petroleum* and *phylloxera* have become domesticated along with the objects which they represent. There are scores of animals, like the *Rhinoceros, Hippopotamus*, and *Ichneumon*, for which there are no English vernacular names; while the youngest student of botany accepts *Hepatica, Anemone*, and even *Rhododendron* without difficulty or hesitation. Homely as it sounds, *stomach* is a strictly classical word, and the use of *caul* for *omentum*, or *sweetbread* for *pancreas*, would surprise a class in elementary physiology.

Even the late Jeffries Wyman, who saw no objection to *forearm*, and used *near* rather than *proximal* for the first row of *carpalia*, accepted *intermembral* as "good," and freely employed, if indeed he did not originate, the adjective *pretibial*, which probably would have come into general use had not the bone in question proved to be the homologue of the *intermedium*.—(Morse, 18, 13).

THE LIMITS OF TERMINOLOGICAL CHANGE.

As has been stated already, the modifications here proposed are intended to provide for what seem to be actual necessities, irrespective of purely theoretical considerations, and of any desire for a perfectly uniform and consistent terminology. It may be well, however, to specify certain general limitations to changes of anatomical nomenclature.

Priority is practically of little moment in respect to the names of organs, since it is usually difficult to ascertain when and by whom they were first applied. An example of this is afforded by the phrase *foramen of Monro*, (Wilder, 3). Nor, indeed, has priority always been held sacred in systematic zoology. Owen's "Deinosaurians" was proposed nine years later than von Meyer's "Pachypoda;" yet, as stated by Huxley (108, 33), it has been retained, notwithstanding the small size of some members of the group.

Etymological appropriateness is sometimes disregarded, as in the case just mentioned, and in the more familiar names *Reptiles, Vertebrates, Edentates*, &c. Prof. Huxley has recently expressed the common sense view of the matter as follows:

"If well understood terms which have acquired a definite scientific connotation are to be changed whenever advancing knowledge renders them etymologically inappropriate, the nomenclature of taxonomy will before long become hopelessly burdened." (B, 751.)

So, too, the names of organs have sometimes been given in reference to some variable or unessential character, or have even represented an erroneous idea; yet no one now thinks of discarding either *rectum, arteria*, or *carotid*.

Sometimes even brevity and etymological accuracy yield to established usage. The word *cubitum*, proposed by me in 1872 (10, 21) as the technical equivalent of *forearm*, is both shorter than *antebrachium*, and more in accordance with its classical employment; but the latter word seems to be more generally preferred, and I am ready to accept it.

In another case, even though a new term has not yet come into general use, a special vitality may be imparted to it by the authority of those who may have adopted it. No marked or persistent disfavor is likely to be shown to terms which, like *myelon*, can claim Prof. Owen as father, and find a god-father in Prof. Huxley.

MESON, ITS DERIVATIVES AND CORRELATIVES.

The present tendency of accurate anatomical description is to refer the position or direction of all parts and organs to an imaginary plane dividing the body into approximately equal right and left halves; hence it is desirable to designate this middle plane, or any line contained therein, by a word which is at once significant, short, and capable of inflection. Dr. Barclay proposed *mesion*, and *mesial* has been generally used; but would it not be better to adopt the very term employed by the Greeks to signify the middle, *meson*, τό μέσον, equivalent to the more ponderous Latin *meditullium*? The corresponding adjective is *mesal*, and the adverb *mesad*, while in combination it becomes *meso*.

The following general terms were also proposed by Barclay, and have been more or less systematically employed by Owen, Huxley and others: *Dorsal, ventral, dextral sinistral, lateral*, with the corresponding adverbial forms *dorsad*, etc. Should the alleged correspondence of the ventral region of the vertebrate with the tergal region of the arthropod prove to be one of true homology, it may be desirable in time to discard *dorsal* and *ventral* for more suitable terms, but for the present, if on practical grounds alone, it seems well to retain them.

CEPHALIC AND CAUDAL.

Barclay proposed *atlantal* and *sacral* for the designation of the position of parts lying toward the head or the tail in reference to an imaginary plane dividing the trunk at the middle of its length. But these terms were not applicable to parts beyond the atlas and the sacrum, so that new words were applied to the regions of the head. Perhaps this needless complication has hindered the general adoption of Barclay's nomenclature notwithstanding its many admirable features. At any rate, *cephalic* and *caudal* are much more acceptable terms, and are practically unobjectionable, although certain theoretical difficulties readily suggest themselves.

Proximal and *distal, central* and *peripheral* are in common use, and the general employment of their inflections and derivatives is only a question of time.

Ental, and *ectal* are here first proposed as substitutes for the more or less ambiguous words *inner* and *outer, interior* and *exterior, deep* and *superficial, profound* and *sublime*. Derived respectively from ἐντός and ἐκτός their significance is obvious, while their brevity and capacity for inflection will probably commend them to accurate working anatomists.

DESIGNATION OF THE REGIONS OF THE LIMBS.

Barclay's terms *ulnar, radial, tibial* and *fibular* refer to only two of the four aspects of each limb. Prof. Huxley has made the very important suggestion that, for comparison, all vertebrate limbs be regarded as placed in a *uniform normal position;* they are then extended laterad at right angles with the meson, with the convexities of the knee and elbow directed dorsad. Each limb then presents not only a proximal and a distal portion, but four general aspects, *dorsal, ventral, cephalic*, and *caudal*. Hence there appears to be no need for the introduction of the new terms employed to some extent by Huxley and other English anatomists, *epaxial, hypaxial, preaxial*, and *postaxial*. These words are also liable to misconception because *axial* has been used already in reference to not only the axis vertebra, but also the entire skeleton of the trunk as contradistinguished from that of the limbs.

DESIGNATION OF CURVATURES.

Ordinary descriptions of the directions of curvatures are apt to be ambiguous, and Huxley resorts to the phrase "arcuated outwards" to indicate the form of the mandibular rami of the Balænoidea. Since the Latins designated the two malformations of the legs, "knock-knee" and "bow-legs," by the words *varus* and *valgus* respectively, we may find it convenient to speak of parts whose convexities look mesiad as *varate*, and of those whose convexities look laterad as *valgate?* In other cases, however, and perhaps even in these, so long as there is any opportunity for misapprehension, it will be well to describe curvatures as *presenting a convexity* in one or another direction. For instance, the mandibular rami of the Balænoidea present a *laterad convexity*, while those of the Physeteridæ are convex toward the *meson*.

HYPOCAMPA.

This is employed by Vicq D'Azyr in the descriptions of the plates of his Traité D'Anatomie, published in 1786. The more common form *hippocampus* occurs in the list of anatomical terms in the same volume, but this may have been compiled partly by others, while the descriptions are obviously the work of the anatomist himself. Vicq D'Azyr does not discuss the etymology of the term, but says the "grande hypocampe" was first mentioned by Arantius and Varolius, whose works are not now accessible to me. Even Hyrtl does not seem aware of the use of the word by Vicq D'Azyr, and all other writers, so far as I know, make it *hippocampus*.

If the original orthography cannot be ascertained, *hypocampa* is to be preferred on etymological grounds; the ridges known as *hippocampus major* and *h. minor* bear no obvious resemblance to the fish known to the ancients as ἱππόκαμπος and *hippocampus*, but the larger of the two, which probably first received the name, does certainly present a most notable *downward curvature*, such as the Greeks might have designated by ὑποκαμπή.

DESIGNATION OF THE ENCEPHALIC CAVITIES.

As based upon the condition of things in man the current nomenclature of the ventricles had some slight foundation. But, in the light of better methods and more accurate knowledge, it appears incongruous and needlessly perplexing.

Let the learned anatomist lay aside his familiar acquaintance with the parts and their names, and put himself in the place of the beginner who, after gaining a general idea of the arrangement of the vertebrate brain from a frog or menobranchus, is trying to master the complexities of the mammalian organ from the brain of the cat, dog or sheep.

Leaving the myelon, he finds the *canalis centralis* expanding into a cavity which, although the first of the series, is called the *fourth* ventricle. The more or less distinct cavities corresponding to the cerebellum and the *lobi optici* are not called ventricles at all, and the *third* is between the thalami. The two "lateral" ventricles are rarely mentioned as the *first* and *second*, but since the numbers must be understood in order to account for the *third* and *fourth*, the student desires, in vain, to know which is the first and which the second. In point of fact, if the enumeration is begun at the cephalic end of the series, the lateral ventricles are the third and fourth, since there are well-developed ventricles in the *lobi olfactorii*. Finally, a "*fifth* ventricle" is mentioned, which is not only at the greatest distance from the fourth, but has no normal connection with the other ventricles, and is, in fact, no part of the series.

In view of all this, the task of describing to students the highways and by-ways of the brain,—which should be most attractive because therein is most clearly manifested the ideal arrangement of the organ,—is one from which I shrink as from any other kind of solemn nonsense. To my mind, indeed, rather than go on as we have been going, it would be at once more philosophical and more intelligible to adopt the simple vocal device employed by Straus-Durckheim for the designation of the metatarsalia—"padion, pedion, pidion, podion, pudion"—and to re-christen the ventricles by, for instance, the names *pran, pren, prin, pron*, and *prun*.

Fortunately, however, another alternative is presented. Whatever objections may be urged against them on theoretical grounds, a real practical advantage is gained by the use of the terms *rhinencephalon, prosencephalon, diencephalon, mesencephalon, epencephalon*, and *metencephalon*, and their German or English equivalents are likewise often employed for the designation of the general regions of the brain. Assuming that these terms are to be retained, and that they are to be learned by successive generations of students, why should we not transfer the distinctive prefixes to the Greek word for ventricle, *cœlia*, κοιλία? This would give us *rhinocœlia, procœlia, dicœlia, mesocœlia, epicœlia*, and *metacœlia*.

These terms are capable of inflection, and the longest of them is no longer than the Latin *ventriculus*, which requires a prefix or qualifying word. Lastly, but by no means of least importance, they correspond with the names of the encephalic segments. As will be seen in the list of names of the parts of the brain, these prefixes are employed for the designation of the membraneous roofs of the "third" and "fourth" ventricles, and the plexuses of these and the lateral ventricles. After a somewhat prolonged consideration of the matter, it seems to me that the practical usefulness and logical consistency of these new terms outweigh any objections that may be urged, and that these latter are less numerous and serious than could be brought against any other substitutes for the present heterogeneous and ill-applied nomenclature.

Two or more ventricles may be spoken of as *cœliæ*, while the "fifth" may be called *pseudo cœlia*. I hope, before long, to justify more fully the proposition already made* to consider the cephalic portion of the "third" between the *portæ* (foramina Monroi), as a morphologically independent cavity under the name of *aula*.

RHINEN, ETC.

May not *rhinen., prosen., dien., mesen.* and *epen.* be written, for the sake of brevity, for the full titles of the general divisions of the brain, *rhinencephalon, prosencephalon*, etc?

* Proceedings of the Am. Assoc. for Adv. of Science, Aug. 25, 1880 reported in "New York Medical Record."

The following abbreviations are printed in Webster's Dictionary without the period: *etym(on)*, *demirep(utation)*, *grog(ram)*, *hyp*,* and *hypo(chondria)*, *noncon(tent)*, *hyper(critic)*, *navvy* for *navigator*; but the abbreviations above suggested should probably be followed by the period.

PRÆCOMMISSURA, ETC.

The single words ***præcommissura***, ***medicommisura***, and ***postcommissura*** are proposed as substitutes for the compound terms *commissura anterior*, *medius*, and *posterior*, and for their English equivalents. A similar change is desirable in the case of the three cerebellar peduncles, which may be more conveniently termed ***præ- meso-*** and ***postpedunculus***. So, too, the *corpora geniculata* (*external and internal*) may be called ***prægeniculatum*** and ***postgeniculatum***; the *brachia* of the mesencephalon become ***præbrachium*** and ***postbrachium***, and the two "perforated spaces," ***præperforatus*** and ***postperforatus***. The "anterior pyramids" have been called by Owen "prepyramids," but more exact designations of these and of the "posterior pyramids" would be ***ventripyramides*** and ***dorsipyramides***.

The prefixes are usually employed when the object referred to lies before, between, or behind other objects of a different kind; *e. g.* ***præcordia***, ***mediterraneus***, and ***posterganeus***. The use here proposed is as if three dogs in line were designated by ***præcanis***, ***medicanis*** and ***postcanis***. If the terms are objectionable, what can be substituted for them? They are certainly as legitimate as are the well-established terms ***prosencephalon***, ***mesencephalon*** and ***metencephalon***. Do not the English words ***preposition*** and ***postposition*** offer some analogy?

The following points are mainly etymological and orthographical rather than anatomical.

THE CONNECTING VOWEL.

With derivative words the connecting vowel is commonly ***i***; ***e.g. alipes, claviger, fatifer, fidicen, fluctigena, decimanus, neurilemma***, and ***xiphisternum***. But classical exceptions are ***mulomedicus, quadrupedus, noctuvigilus***, and ***decumanus***. In common English and scientific terms of Latin or Greek origin the *o* is common; *e. g.* ***ambodexter, burgomaster, gastrotomy, termonology, ventroinguinal, lateroflexion, mucopurolent, vasomotor, curvograph, neuroglia, oculospinal, pleuroperitoneal, xiphosura, septopyra, hemoglobin, cephalotribe***, etc. Rarely is it ***e*** as in *venesection*.

Should the *i* or the *o* be used in the following terms: ***Dorsimeson, ventrimeson, dorsicumbent, latericumbent, dextriflexion, sinistriversion, cephaloduction, caudiduction***, etc.? Both analogy and euphony lead one to use the ***i*** when the first part of the word is of Latin origin, and the ***o*** with the Greek.

Should any of these terms be written as compound words?

COMPOUND WORDS.

The two Latin compounds known to me are *veneri-vagus* and *vesti-contubernium*. The following common or technical English compound words are selected from Webster's English Dictionary, or the Medical Dictionaries of Dunglison, or Littré et Robin, or from the writings of Barclay, Humphrey, and Straus-Durckheim: *Anglo-Saxon, concavo-convex, dextro-gyrate, ventro-appendicular, costo-vertebral, costo-alaris, caudo-pedal, osseo-cutaneous, occipito-scapularis, dorso-lateral, sterno-clavicular, clavo-cucullaire, clavi-sternal, clavio-humeralis*. By analogy with the foregoing, compound terms of direction should read *dorso-ventral, caudo-cephalic, meso-lateral, sinistro-cephalic*, etc.

HYBRID WORDS.

Some of the terms already mentioned are formed by the union of Latin with Greek words; *e. g.*, *dorsimeson, meso-lateral*, and *caudo-cephalic*; several others are likely to be employed; *e. g. clavo-mastoideus*, and *felitomy*.

Beyond the occasional intimation, in the dictionaries, that a term is hybrid, the subject seems to be ignored, and it might fairly be inferred that literary authorities entertain one or the other of two opposite convictions: either mongrel words are verbal monstrosities which will be shunned instinctively by all well-regulated minds, or there is no more serious objection to their use, or even their creation, than to the employment, or even the production, of mules, or the mixed varieties of grapes and roses.

However this may be, the fact is that the Latin and the Greek tongues have united to form the following nine hybrids which may be found in Latin writings: ***anticato, biclinium, cryptoporticus, dentarpaga, epitogium, monosolis, monoloris, pseudo-flavus***, and ***pseudo-urbanus***. Of these, the third only occurs with any degree of frequency.

Whoever will spend the time to look through an unabridged dictionary of the English language—and the interest as well as the instructiveness of such a search can hardly be realized by those who use the volume only for occasional reference—will find that, after excluding the twenty-five or more words ending with ***meter***, which may perhaps be derived directly from the Latin form ***metrum***, there are more than ***one hundred hybrid*** words, many of them in good standing. Many more are to be gleaned from the dictionaries of medicine and the other arts and sciences.

Nevertheless, it is probable that a due regard for the feelings of the classical purists in whose eyes language was not made for man, but rather man for language, will lead scientists to refrain from the introduction of mongrel terms when others will serve the purpose, and the present writer will be pleased to receive suggestions leading to the substitution of wholly unobjectionable words for any of the hybrids which have been mentioned.

(*To be continued in our next.*)

ON CHICKEN CHOLERA: STUDY OF THE CONDITIONS OF NON-RECIDIVATION AND OF SOME OTHER CHARACTERISTICS OF THIS DISEASE.*

By M. L. Pasteur.

II.

Concerning the properties of the extracts of the artificial cultivation of the germ of chicken cholera, an inquiry presents itself. We have shown that these extracts contain no substances capable of preventing the cultivation of the germs of this disease. They might, however, contain elements adapted to the vaccination of chickens. To investigate this point I have prepared cultivations where volume was not less than 120 c.c. After filtration and evaporation at a low temperature, while infinite care has been taken that its purity should not be affected, this liquid has given a dry extract, which was re-dissolved in 2 c.c. of water, and the totality of this was injected under the skin of a chicken which had never had chicken cholera. A few days afterwards the chicken, after being inoculated with a virus of the greatest virulence, died with the usual symptoms of ***unvaccinated*** chickens.

This class of experiments led to the following observation, which is of the greatest importance in physiology. When the extract from the cultivation of the germ of this disease, corresponding to an abundant development of the parasite, is injected under the skin of a fresh chicken in perfect health, the following phenomena take place: At first the chicken seems to suffer from a nervous dis-

*Translated from the *Comptes Rendus de l'Academie de Sciences*, of May 3d, 1880, by P. Casamajor. The translation of the second paper of this series appeared in the *Chemical News*, vol. xlii., page 321 (December 31, 1880).

order, which is indicated by panting breath and alternately opening and closing its beak; afterwards it becomes motionless, assumes the shape of a ball, refuses food, and seems overcome with drowsiness, as is the case with chickens affected with the disease. There is this difference, however, that the chicken wakes up at the least noise. This sleep lasts about four hours, after which the chicken wakes up, looks as well as usual, eats and cackles as if nothing had happened to it.

I have repeated this experiment several times and have always observed the same facts. Before injecting the extract above mentioned, I took, in every case, the precaution of injecting an extract of the pure chicken broth, which does not cause analogous phenomena. I have, by this means, acquired the conviction that, during the life of the parasite, a narcotic is formed, and that it is this narcotic which causes the morbid symptom of sleep so characteristic of the disease which we are studying.

By the acts of its nutrition the germ of the disease causes grave disorders and brings on death. The germ, being aerobian, absorbs during its life large quantities of oxygen, and burns up many of the elements of its medium of cultivation. This may be seen by comparing the extract of the broth, before the development of the germ, with the extract of the liquid in which the development has taken place. Everything seems to show that it is from the globules of the blood that the oxygen necessary to its existence is derived by absorption through the tissues. While the chickens are still alive, even when death is still far off, their combs assume a violet tinge at a time when the germ of disease is so little diffused through the blood that it escapes microscopical examination. This species of asphyxia is one of the most curious traits of the disease we are studying. Death is caused by the grave disorders brought about by the development of the parasite in its body, by pericarditis, by serous extravasations, by alterations of its internal organs, by asphyxia, but the sleep characteristic of the disease is caused by a product formed during the life of the germ, which acts on the nervous centres. The independence of these two effects in the symptoms of this disease is further established by the fact that the extract from a filtered cultivation of the germ acts as a narcotic on chickens which have been submitted to the *maximum* degree of vaccination.*

These facts will, doubtless, be found worthy of the meditations of pathologists.

Although I have taken already much of its time with this subject, the Academy will allow me to call its attention to some other characteristics of the disease called *chicken cholera*. We know that this disease is rapidly fatal, particularly if caused by a direct inoculation of its germ. It must then appear extraordinary that it sometimes presents itself in the chronic state, as in the case of inoculated chickens; which, after being severely ill, do not die, but seem to get relatively better. They eat, however, very little; they become anæmic, as shown in the discoloration of their combs; they continue to lose flesh, and finally die, after lingering for weeks or months. This fact would not be of primary importance if, at the death of the chicken, the germ of the disease was not, in most cases, found in its body, which conclusively proves that the parasite has been present since the last inoculation, always active, although in a mild form, for it brings on death slowly. Doubtless, the germ was placed in some *vaccinated* portion unfavorable to its cultivation. Vaccinnated chickens are most apt to present this form of disease, which is of very rare occurrence. We might be led to believe that, in this case, the virulent virus is changed into the attenuated, but this would be an error. In cases of this kind the virulence of the germ of the disease seems, on the contrary, to be aggravated. This may be easily seen by cultivating it artificially, so as to separate it from the blood, and inoculating it on fresh chickens.

Facts of this kind help us to understand the possibility of those long incubations of virus, such as that of rabies, for instance, which, after existing a long time in the body in a state which may be called latent, suddenly manifest their presence by the most marked virulence and by death. Do not these facts also throw light on human pathology?

Alas! how often we see virulent diseases, such as scarlatina, measles, typhoid fever, followed by serious disorders of long duration, which are frequently incurable? The facts to which I have called attention are of the same nature, only here we can put our finger on their true cause.

I will conclude by pointing out another peculiarity, which is not less worthy of the attention of the medical profession.

In chickens in perfect health which have been thoroughly vaccinated there often occurs an abscess full of pus on some portion of the body, which does not seem to have any injurious effect on the health of the animal. It is a remarkable circumstance that this abscess is due to the germ of chicken cholera, which remains in it as in a closed vessel, and it cannot propagate, doubtless, because the chicken has been vaccinated. This germ may be withdrawn by artificial cultivation, or it may be directly inoculated on fresh chickens, which it kills in the usual manner after an abundant development. These facts recall the abcesses on guinea-pigs, which I have mentioned in the first communication on this subject, and they furnish a rational explation of what happens in these abcesses. In all likelihood the muscles of the guinea-pig cultivate the germ more slowly and with greater difficulty than those of chickens; the disease is limited to an abscess, and recovery becomes possible.

I will now conclude this statement, as I have no wish to wear out the patience of this Academy. This subject is, however, so vast and so fruitful that I will ask its permission to bring the subject before it again. I have other observations to present than these. I will add those which will present themselves in the investigations I am now making.

"We would give nothing to the public," said Lavoisier, "if we waited until we reach the end of our researches, as these become broader and more extended the farther we advance."

* I should, however, try to isolate the narcotic, and see whether a sufficient quantity could cause death, and whether, in this case, the internal disorders would be the same as those of the disease itself.

THE NEW CHEMISTRY.

Lieut.-Col. W. A. Ross, who has done so much to advance our knowledge of blowpipe analysis, and whose original chemical investigations are of the greatest interest, in speaking of Prof. Cooke's "New Chemistry," indicates as follows, that much more radical changes, at all events as regards anhydrates, will shortly demand the attention of philosophical chemists, in consequence of the following facts:

FACT 1. 5mgrs. of pure caustic lime are carefully fused into a bead of pure boric acid before the blowpipe, the bead boiled in distilled water, and the transparent calcium borate ball thus extracted, weighed. The weight will invariably be exactly 20mgrs.

FACT 2.—The above-mentioned ball is now fused into a second bead of boric acid, the transparency of which it does not in the least degree affect, and when again boiled out it has the same weight—viz., 20mgrs.

FACT 3. —5mgrs. of calcium hydrate are now fused into a boric acid bead similarly to (1), when it is observed that the borate ball formed is at first opaque white; then, as it becomes transparent B B, that an enormous amount of opalescent matter is emitted from the ball into the bead; and finally, that the extracted ball weighs only 15mgrs.

FACT 4.—The calcium borate ball (2) is now held as a bead *per se* on platinum wire, and 2.5mgrs. of pure silica, or of rock crystal, dried at red heat, dissolved in it B B: after which the silicious ball is weighed, and added B B to a boric acid bead, which it NOW *renders opaque with opalescent matter;* finally, the extracted ball, when weighed, showed, in an average of three assays, an increase in weight of 42 per cent.

FACT 5.—5mgrs. of pure "anhydrous" silica (SiO_2) are carefully taken up on a bead of pure boric acid, and observed to be absolutely unalterable there, B B. A weighed ball of anhydrous calcium-borate is now added B B to this bead, when the silica is gradually decomposed —the weight of the ball being unaltered—not into silicon and oxygen, but into really anhydrous silica (*which possesses extraordinary electrical properties*), and some compound of hydrogen, which makes the bead opalescent. After boiling, only 2mgrs. of residue are obtained.

Now these five facts, and more especially the immense increase in weight of the silicious calcium-borate ball (4), notwithstanding the great loss of matter causing opalescence, show that there is an enormous percentage, nearly half, of SOME COMPOUND OF HYDROGEN, not eliminable as gas, existing in what has been hitherto supposed to be an anhydrous substance, which has escaped even the closeness of modern chemical analysis, for the simple reason that the water solutions of acids and alkalies used to analyse, themselves contain this very compound of hydrogen.

Many confirmatory proofs of this startling truth have been afforded, but cannot be detailed here, because the details form part of the subject of a competitory essay, and cannot yet be published.

Hydrogen, however, in this solid form, can now be proved to be an almost omnipresent component—of all so-called "anhydrous" minerals, of most artificial as well as natural inorganic productions, of many so-called "elements," and, to my mind, of the galvanic "currents" themselves.

Thus it is seen that the beautiful and immaculate theory of combining proportions, first enunciated in 1777 by the illustrious Wenzel in his "Lehre Von der Verwandschaft der Körper," relates entirely to hydrates, and that a new chemistry, the chemistry of anhydrates, now requires to be studied.

Let us hope that some future Wenzel and Dalton will apply proportional and atomic theories to this anhydrate chemistry, and now that the first dawning of the truth has at last been published in Germany and America as well as here, we cannot doubt that this will soon be done.

It remains, now, an unpleasant part of my duty to point out that, although I supposed, by the discovery of the above mentioned facts, I had laid the first foundation of what must, sooner or later, be adopted as a new and essential study by everyone who aspires to the title of a philosophical chemist, I found I had been anticipated in my most important deductions by no less a man than Joseph Priestly.

That unfortunate genius—in repeating one of whose experiments with a more powerful electric battery, Sir Humphry Davy discovered potassium—has been so utterly misrepresented by the modern school of chemists, which has elevated Lavoisier in his place as the founder of the chemistry of hydrates, that it would take more time than you and I can afford, to adduce in proof, a quarter of their misrepresentations.

I will give just one instance. Prof. Cooke, in the book called "The New Chemistry," says (p. 98): "Iron, in rusting, gains in weight, 'Hence,' said Lavoisier, 'it has combined with some material.' 'No,' said such men as Cavendish, Priestley, and Scheele, 'it has only lost phlogiston, which differs from your gross forms of matter in that it is specifically light, and, when taken from a body, increases its weight.' We smile at this idea," etc.

Now what does Priestley himself say?—See p. 249, Vol. I., "Experiments and Observations," sect. IV., "Inflammable Air."—"It was even asserted by some that phlogiston was so far from adding to the weight of bodies, that the addition of it made them really lighter than they were before, on which account they chose to call it the principle of levity!" Priestley says here, that he "discovered phlogiston to be hydrogen by direct experiments."

Then follow those celebrated experiments—so much neglected and concealed by modern chemists—in which Priestley converted a certain quantity of lead oxide into a certain quantity of lead "by throwing the focus of a burning-lens upon it through a glass receiver filled with a certain quantity of "inflammable air"—or hydrogen.

It may be fashionable now to "smile at the ideas of such men as Cavendish, Priestley and Scheele"; but it seems to me much more reasonable to smile at the ideas of Lavoisier and his disciples, who did not seem able to understand the possibility of a compound losing (by means of heat or other factor in the operation) an extremely light constituent, and taking up, instead of it, another surrounding constituent sixteen times as heavy, whereby the aggregate weight of the compound would, of course, be increased by the coefficient fifteen.

In precisely the same way I have proved, by my humble experiments, that a ball of calcium-borate, having silica (for instance) dissolved in it, increases enormously in weight by treatment in boric acid B B, although it obviously loses a large quantity of hydrogenous matter, which renders the whole bead opaque white; simply because the compound acquires, instead, a much heavier constituent—viz., boric acid.

We invite those who are interested in the blow-pipe analysis who desire any information on the subject to address a letter to "SCIENCE," as Col. Ross is one of our subscribers, and appears always ready to aid those who require instruction. A letter to "SCIENCE" will doubtless receive prompt attention.

THE AMERICAN CHEMICAL SOCIETY.

The March meeting of the American Chemical Society was held on Monday evening, the 7th inst., Vice-president Squibb in the chair. The resignations of the following gentlemen were read and accepted. Messrs. Elihu Root, H. G. Smith, F. Alexander, J. T. O'Connor, and also, in consequence of its interference with his business, the Recording Secretary Dr. A. H. Gallatin, tendered his resignation from office. Mr. Theodore Tonnelé and Mr. J. G. Mattison were nominated for membership. The reading of papers followed, the first of which "A New Specific Gravity Bottle" by William H. Gregg, was read by Dr. A. Behr. The essential difference between the ordinary bottle and the one devised by Mr. Gregg consists in that the latter has an expansion or bulb just above where the stopper is, in the regular form. A thermometer serves as a stopper passing through the bulb sealing it at both extremities. The advantage of this improvement is that the liquid cannot run over or volatilize (in the case of essential oils, etc.,) for it will be retained in the bulb which is stoppered at each end by the thermometer.

The second paper was by Dr. J. H. Tucker, "On the solvent action of carbonic anhydride in solution upon various bodies under different conditions as to temperature and pressure." The methods of manipulation were first detailed, after which the effect upon the "various bodies," these being chiefly mineral, was described. Mr. Casamajor followed with some observations upon the difficulty that he had experienced in obtaining hydrogen sulphide from impure iron sulphide. After some experimenting he found that upon adding a little zinc amalgan, alopians evolution of the gas ensued. By this method he was successful in obtaining excellent results with galena, orilcopyrite and pyrite.

Mr. J. H. Stebbins, Jr., called the attention of the society to several new coloring materials that he had discovered among the di-amido compounds. They were yellow in color and suitable for silk, woolen and cotton dyeing, but especially desirable for the latter.

Dr. A. R. Leeds gave a short description of some new experiments on the action of hydrogen peroxide with ammonium hydrate.

A committee consisting of Mr. Casamajor and Dr. Alsberg were appointed to make arrangements for the annual dinner. M. B.

NEW YORK, *March* 9, 1881.

IMPROVED PORTABLE EQUATORIAL STANDS.

By JAMES H. GARDINER.

The stand I use, and those which I have seen, have no levels and no means by which the telescope can be moved in azimuth without moving the whole stand. It seems to me that, with a very little trouble, these stands could be made not only a great deal more accurate, but also much more useful for amateur work by the following additions: Instead of having the equatorial mounting screwed firmly to the lower plate to which the legs are attached so the telescope cannot be moved in azimuth without moving the whole stand, a plate could be ground to touch, say, only ¼ of an inch, and revolved on the lower plate. This would give a steadier and easier motion, with less friction than if the two plates were ground to touch all over. A thread is to be cut in the side of this upper plate, so that with a tangent screw it can be moved in azimuth. On this upper plate that revolves on the lower plate, and to which the tangent screw is attached, should be placed two levels at right angles to each other, and then on this upper plate that revolves the usual equatorial mounting is to be firmly fastened. It will be seen that the above stand only differs from the usual stands on tripods, in having levels and means to move the telescope in azimuth without moving the whole stand. Such a stand would be of great use to amateurs, who have a poor horizon, and are obliged to move their stands about to command all parts of the heavens; or for those who may have a good horizon, but cannot afford the luxury of a fixed pillar and dome. The use of such a stand will appear from the following illustration; Suppose the observer has such a stand, and that he is at Washington, and on the 1st of March, 8 P. M., he desires to put his telescope in the meridian. He carefully levels the stand, and turns his telescope on *a Polaris* to come into the centre of the field. If it does not happen to come exactly in the centre of the field, he can raise or lower his polar axis, or move the telescope in azimuth by aid of the tangent screw. Here it is to be noted that with the old stands he would have to twist the whole stand around and throw it out of level, and by repeated trials get *a Polaris* in the centre of the field, and when he again levelled the stand *a Polaris* might not be in the centre of the field. Thus every movement of the old stand would throw it out of level. All these tedious trials are obviated by the new stand with azimuth motion. When once levelled it would stay so, and the telescope could be moved to the east or west without having to be continually bothered with levelling it. Thus in a few moments he would have *a Polaris* in the centre of the field, and the telescope approximately in the meridian. He now reads his R. A. circle, and turns his telescope on some well known star, as *a Leonis* or *Regulus*, for example, and then reads his R. A. circle again. Supposing the difference of these two readings of the R. A. circle to be 3h. 25m. 13s., this is the observed hour-angle of *Regulus*. The true hour-angle of *Regulus* is equal to the difference of the Sidereal time and the R. A. of *Regulus*, or 3h. 22m. 13s. This shows that the object-end of the telescope must be moved 3m. to the west to make the observed hour-angle agree with the true hour-angle. This can be done nicely by the targent screw that moves the telescope in azimuth without throwing it out of level, but with the old kind of stand it would be thrown out of level, and it would be a very tedious job, requiring time and patience to accomplish. Having got the telescope very nearly in the meridian, the declination circle can now be set to the δ of the star. With such a sand the careful amateur can put it near enough in the meridian to pick up a comet or any other object by its R. A and δ. The accuracy of the adjustments depends upon the levelling, the collimation, and an exact value of the local time. The levelling would generally be accurate enough, and most stands have screws in the saddle that carries the telescope for correcting the collimation. But the amateur should try to get the exact value of his local time, as this would probably introduce the greatest error. This can be done by equal altitudes of the sun or star. Or where the latitude of the place is well known the local time may be found by an altitude of the sun. With such a stand as has been described, if it should be necessary to move it to another place, it could easily be put in the meridian again, as described. Besides, many have stands with good circles which they seldom use, because they cannot afford a fixed pillar and dome, and do not care to put it in the meridian, as they are obliged each night to bring the telescope into the house. But if it could be put in the meridian easily, I am sure many would be pleased to use their circles.

ASTRONOMICAL MEMORANDA.

[Approximately computed for Washington, D. C., Monday, March 21, 1881.]

Sidereal time of mean noon, 23^h, 57^m, 24^s. Equation of time, 7^m, 8^s. Mean noon *preceding* apparent noon.

On the morning of March 20th, the sun crosses the equator and enters the constellation Aries, thus indicating the commencement of Spring. The violent actions upon the sun's surface have continued throughout the past month.

The *moon* reaches its last quarter on March 22, and is new again on the 29th. On March 21st, she crosses the meridian at 4 A. M. The moon will be in conjunction with Mercury on the 27th, and with Jupiter and Saturn on the morning of the 31st.

Mercury is morning star, crossing the meridian about an hour before the sun, nearly 6 degrees farther south. Mercury was in inferior conjunction with the sun on the 11th and is travelling towards the west.

Venus has been moving westward since her greatest eastern elongation on the 20th of February, and will continue to increase in brilliancy till March 27th. She crosses the meridian at about 2.40 P. M., about 20 degrees farther north than the sun.

Mars, crossing the meridian nearly 3 hours in advance of the sun, is coming towards us, and gradually increasing in brilliancy.

Jupiter crosses the meridian at about 1.15 P. M., and *Saturn* 15 minutes later. They are both becoming very unfavorably situated for observation, and must be looked for immediately after sun-set.

Uranus is in right ascension 10^h, 50^m, 47^s; declination 8° 14′ north, and was in opposition on March 1st.

Neptune, right ascension 2^h, 47^m, 17^s; declination 13° 56′ north. Neptune and Venus are in conjunction on the 23rd.

THE following is a list of the officers and council of the Royal Astronomical Society, elected February 11, 1881:— President: J. R. Hind; Vice-Presidents: Prof. Cayley, E. Dunkin, W. Huggins, E. J. Stone; Treasurer: F. Barrow; Secretaries: W. H. M. Christie, J. W. Glaisher; Foreign Secretary: the Earl of Crawford; Council: Prof. Adams,

Sir G. B. Airy, J. Campbell, A. A. Common, G. H. Darwin, Major J. Herschel, E. B. Knobel, G. Knott, A. Marth, E. Neison, A. C. Ranyard, Prof. H. J. S. Smith.

THE gold medal of the Royal Astronomical Society has been presented to Prof. Axel Möller, Director of the Observatory at Lund, in Sweden, for his investigations on the motion of Faye's comet. W. C. W.

WASHINGTON, March 18, 1881.

MICROSCOPY.

On looking over the Transactions of the New Zealand Institute for 1878, we notice that a Mr. A. Hamilton speaks of having discovered *Melicerta ringens.* It was found in great profusion,on the finely-divided leaves of the *Myriophyllum.* This adds another locality to the wide geographical distribution of this interesting Rotifer.

Mr. Hamilton states that after examining a number of specimens he found the description given by Gosse correct, except that the formation of the pellets was at a much slower rate than that stated by him.

In the same locality were also found organisms which Mr. Hamilton thought to be *Plumatella repens;* they were growing on dead thistles in a swamp in only a few inches of water.

The American Monthly Microscopical Journal for March editorially announces the immediate publication of Mr. F. Habirshaw's Catalogue of the Diatomaceæ, also by the editor, a small book based on Professor J. Leidy's "*Freshwater Rhizopods of North America.*" The editor's handbook on Adulteration is withdrawn.

In the same number Dr. F. S. Billings gives a long resumé of what is known about "*Trichenæ,*" but seems to offer no new facts; the illustration he offers of "*Fresh trichinous invasion*" (after Heller) is a wretched misrepresentation of free trichinæ.

Any reader desirous of examining living specimens of trichinæ in this condition can obtain them on calling at our office.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE:"

The development of a peculiar non-nervous tissue in connection with the rhomboid sinus of the lumbo-sacral intumescence in birds, and which is especially well marked at the embryonic period, is I think of some bearing on the recently agitated question of a so-called lumbar brain in the extinct sauranodon. In all amniote embryos that I have studied myself, and of which I can find illustrations in accessible works, it is remarkable that there is a distinct posterior enlargement before the cephalic enlargement is well marked, or the brachial intumescence is even indicated in the medullary tube. This fact may point to the potent influence of some, at one time, deeply engrafted ancestral trait. It is not, I think, necessary or warrantable to go beyond this fact, and the established one of the existence of a non-nervous enlargement at the same region in allied sauropsidæ in endeavoring to account for the peculiarity found in the spinal canal of an extinct saurian genus. The supposition of the existence of anything meriting the designation of a brain elsewhere than in the cranial cavity in any amniote animal would be so fundamentally out of harmony with what we have learned to consider as the normal type of structure, that much stronger evidence than the size of a bony receptacle must be adduced before it can even be taken into consideration. That the size of a cavity and that of the contained organ are not neecssarily in close correspondence, has been alluded to by another correspondent under the initials of B. G. W. I have been struck, in this connection, with the discrepancy between the size of the brain cavity and the brain itself in a two year old hippopotamus, though they corresponded in a young elephant.

Respectfully,

E. C. SPITZKA, M. D.

N. Y. 130 E. 50th Street.

To the Editor of SCIENCE:

PARIS, March 5th, 1881.

In bringing before your notice various points which are both novel and interesting, it seems to be my fate constantly to struggle with an *embarras de richesse* represented by a vast combination of phenomena which is forever appearing upon the scientific horizon.

Condensing therefore as much as possible the matter at my command, I will begin with a very trite and commonplace observation; petroleum is a most excellent thing in its way. It is inexpensive and it gives forth a beautiful light. But these advantages, as many know to their sorrow, are more than counterbalanced by the disagreeable habit it sometimes has of exploding. Accidents thus occasioned, frequently prove fatal, as the violence and intensity of the explosion prevent, in most cases, speedy relief being administered to the victims. Besides this, the methods employed are inefficient and usually unsatisfactory.

M. Ichlumberger, whose mind for some time has been occupied with this subject, finally proposes a mode of extinction which is exceedingly simple, and at the same time instantaneous. So confident is he of the efficacy of his plan, that he would like to make a law compelling every one to adopt it who has petroleum in any quantity.

This is his method; Upon every keg or barrel of petroleum, place a moderately large bottle filled with aqua ammoniæ. Should an explosion occur, the shock will shatter the bottle, spread the fumes of the ammonia in the atmosphere, and produce an automatic and infallible extinction of the flames.

This plan can well be recommended to those who make use of petroleum, or who are obliged to superintend the distillation of the liquid. It is only necessary to have within easy access one or several bottles of aqua ammoniæ, whose contents should instantly be scattered upon the petroleum in case it catches fire.

M. Ichlumberger also thinks that this mode of extinction could be effectively utilized in mines where fire-damp is imminent. The ammonia should be put in reservoirs, and so placed that it will be overturned immediately when the explosion occurs. This agent would undoubtedly be more powerful than water, and M. Ichlumberger's idea is worthy of serious attention.

A very peculiar case of poisoning occurred a short time ago at *Puy l'Evêque*, an account of which was sent to the *Académie de Médicine* by Dr. Demeaux. It seems that a family composed of five persons was taken violently ill after having eaten some mushrooms. One of the mushrooms left from dinner was sent by Dr. Demeaux to the *Académie* as a specimen, and upon being examined by M. Chatin, was found to belong to one of the numerous varieties of the *oronge-cigué* species called the *Amanita bulbosa.* Nine-tenths of the mushroom poisoning we hear about is due to this *Amanita* which, on account of its white color is frequently mistaken by the inexperienced and unsuspecting for the harmless mushroom. It is certainly the height of folly for people to run about the woods and fields mushroom hunting, unless they are perfectly familiar with the different species.

Science, it seems, is able to reap some benefit from everything, however trivial! Fancy the ignoble art of Tattooing being elevated to a philanthropic institution! And yet, this is indeed the case. Up to the present day, the artists whose business it was thus to decorate the human skin, confined themselves to tracing merely a warlike emblem in indigo or vermillion upon the arms of our troopers, with the number of the regiment added sometimes. However, their ambition led them to execute a more intricate and ornamental design, such as a flaming heart pierced by an arrow, accompanied by the inscription, "To Mary," or something equally effective. Henceforth, be it understood, these dermographic artists will be looked upon as valuable auxiliaries to surgery.

"Why is it," asks Dr. le Comte, who is physician to a regiment of dragoons, "why is it that such quantities of soldiers die upon the battle field?" And then he replies confidently: "Simply because of the difficulty which arises in regard to arresting hemorrhages,"

The compression of an artery being the best mode of stopping profuse bleeding, Dr. le Comte proposes to teach each soldier first where these vessels are situated, so that he may assist himself while waiting for the surgeon. Therefore, he tattoos an image of some kind upon every portion of the soldier's body where there is an artery. Think of it! Has ever a more ridiculous and absurd idea been put into practice? How infinitely preferable it would be to furnish each soldier with a tourniquet, or at least compel him to attend six lectures upon anatomy, even though such a course might spoil a good soldier to make a bad doctor.

I believe some news has already reached you of Balmain's luminous painting, which attracted public attention some months ago and was first practically applied at the establishment of Messrs. Thlee and Horm. The ceilings of their different offices were covered with a layer of the composition, dissolved in water, and the effect produced is that of a diffused light which is sufficient to enable one to distinguish the various objects in the room.

M. Balmain's idea is excellent, and it would be most advantageous to paint the ceilings of rooms, passages, halls, etc., with his composition, should the use of lamps be dangerous or not absolutely necessary. A simple border of the painting is sufficient in narrow passage ways and stair-cases, and costs a mere nothing.

When dissolved in water, the composition can be applied like whitewash or kalsomine and is useful in more ways than one. Large slabs of glass have been covered with it and employed on board of English marine vessels, also in the Waltham powder factory and in Mr. Young's refinery to illumine places where it is impossible to carry a light. This painting has likewise taken the place of lamps upon several railroads in England, particularly those lines where tunnels are so frequent as to necessitate constant light in the carriages.

Now, a word about meteorology. Nearly every book that has been written on the subject, tells us unhesitatingly that the *Aurora Borealis* is a very rare occurrence except in the polar regions. It appears, however, that this is by no means the case, and that it can be observed with equal frequency in countries occupying a much lower latitude.

M. Sophus Tromholt, of Bergen, Norway, has just published an interesting account of some observations made at his request during the winter of 1878-1879, at one hundred and thirty-two stations extending throughout Sweden, Norway and Denmark. Many extraordinary facts concerning the *Aurora Borealis* can be gathered from this work. To give you an example, it was found that scarcely an evening passed that the phenomenon was not witnessed in one of these countries. M. Tromholt thinks the Aurora is often a local phenomenon, situated but a short distance above the surface of the earth. To strengthen his opinion he quotes many cases in which the Aurora was seen at one or more of the stations without being visible at Bergen, the headquarters, so to speak, where observations were carefully made both day and night. The phenomenon was only seen three times simultaneously by all the stations comprised in 71 and 55 degrees. And even then, who knows but that it was the same Aurora that each saw?

I cannot close my letter without mentioning why the inauguration of the Berlin electric railroad has been so long delayed. As was feared, electricity escaped from the middle rail, and a copper conductor supported by means of stakes has been substituted. Although this is a great improvement, it is doubtful whether the railway can be used in rainy weather, and this fact justifiesan article recently published in *L'Electricité*, which affirms that electric railroads can only be properly employed in tunnels such as, for instance, those of the future Metropolitan in Paris. COSMOS.

VANILLIN.—Meissner's new process for the manufacture of the aromatic principle of vanilla consists in producing it from eugenol $C_{10}H_{12}O_2$ by first forming aceteugenol; then oxidizing the said product with a certain proportion of permanganate of potash in a neutral solution; and, finally, further oxidizing the product with bichromate of potash in a neutral solution. The aceteugenol is obtained by digesting the dry eugenol with an excess of acetychloride C_2H_3OCl. The excess of acetychloride is distilled off, and the remainder used for the production of vanillin. (1). The crude aceteugenol is oxidized in a neutral solution, 47 to 50 parts of permanganate being used to 20 parts of aceteugenol. The product obtained is separated by a filter press from the binoxide of manganese formed during the oxidization, and after the decomposition of the small quantity of the carbonate of potash by sulphuric acid, the clear liquid is evaporated in a vacuum at 50 deg. C., to about 1-15th of the original volume. The acetvanillin is extracted from the lye thus obtained by repeated agitation with ether. (2). The lye freed from the acetvanillin is heated to 100 deg. C. to remove all the ether, and after being neutralized is mixed with neutral chromate of potash. The mixture is heated until the chromate is decomposed, and the product filtered off from the oxide of chromium, and shaken up with ether to remove the acetvanillin formed during the oxidizing process. This operation is repeated on the lye several times. After the evaporation of the ether, the acetvanillin is boiled with soda, by which operation crude vanillin is obtained, which is purified by being dissolved in ether, and shaken up in a warm saturated solution of bisulphite of soda, and set aside to crystallize. The crystals are washed in bisulphite of soda solution and strong alcohol, and finally decomposed by sulphuric acid when the vanillin separates as a colorless oil, and can be finally recrystallized in water.

IN speaking recently of the Washington telescope we inadvertently referred to it as a 32-inch equatorial. This instrument is well-known to have an object glass of 26 inches diameter. The objectives for the Russian Government ordered by Struve is 30 inches, and the Lick equatorial will have a 36-inch objective.

THE CAUSE OF SPONTANEOUS DECOMPOSITION OF RAW CANE SUGAR.—Organisms contained in these sugars multiply and produce an inversive ferment.—U. GAYON.

PERSISTENT VITALITY OF CARBUNCULAR GERMS, AND THEIR PRESERVATION IN CULTIVATED SOILS.—At a farm near Senlis, cattle which have died of carbuncular fever twelve years ago have been buried at a certain spot in a walled garden. Samples of the soil were lixiviated and concentrated, and guinea-pigs inoculated with the matter died quickly with well-marked symptoms of carbuncle. Of seven sheep allowed experimentally to pass a few hours daily on this spot, two died of the same disease in the course of six weeks, whilst the rest of the flock from which the seven had been taken remained healthy.—M. PASTEUR.

BOOKS RECEIVED.

SIR WILLIAM HERSCHEL: HIS LIFE AND WORKS. By EDWARD S. HOLDEN, of the United States Naval Observatory, Washington. Charles Scribner's Sons, 743 Broadway, New York. 1881.

There is a charm which attends the memory of some representative men, and which endears even their history to posterity.

Foremost among such men we recall the name of Herschel, and we could hardly select a more pleasing task than to touch lightly on a few salient points in his eventful career.

In our opinion the great feature in Herchel's history was, that he succeeded in reaching eminence as a scientific man, notwithstanding the apparently insurmountable difficulties that stood in his path to success.

Consider for a moment the position of Herschel when he made his first effort to become an Astronomer. He was 34 years of age, residing in a foreign country where he was unknown, and earning a bare existence as a musician, with a younger brother on his hands, and a sister who was not even acquainted with the language of the country (England) in which they then resided.

They were too poor to hire a servant, and what with out-door performances and giving instruction at home, there was little time for recreation, for even leisure moments were occupied by copying music. So that it was only at night, when he would retire wearily to bed, with a basin of milk, and Smith's *Optics* and Ferguson's *Astronomy*, that he could devote the first thoughts to a science which hereafter must ever be associated with his name.

He would then rise in the morning with thoughts intent on seeing for himself the celestial objects of which he had been reading over night.

To purchase an instrument was out of the question, but with the indomitable energy of will which stamped his career thereafter, he at once determined to make a telescope with his own hands, and not content with striving to see what other observers had observed, he began to contrive a telescope eighteen or twenty feet long.

But to earn an existence by music now occupied every moment, day and night and it was many months before a telescope could be commenced; but finally in 1744, when he was 36 years of age, he completed a Gregorian telescope, and began to view the heavens under circumstances that must have been depressing to a less ardent mind; for he had to contrive a few spare moments as best he could, even running home between the acts at the theatre to make a short observation, and then rushing back to take his position in the band.

And so, with mind divided between the oratorios of the *Messiah*, *Judas Maccabeus*, &c., and the variable star *Mira Ceti*, along with the music went the Astronomy, until on the 13th of March, 1781, Herchel, this amateur astronomical observer of Bath, made one of the most striking discoveries since the invention of the telescope, for in examining the small stars in the neighborhood of H *Geminorum* perceived one which appeared visibly larger than the rest, and this object proved to be the major planet, now calledUranus.

Naturally, this was the turning point of Herschel's life, and his a ter career was a rapid rise to the highest eminence as a scientific man and one of the most accomplished astronomers.

The story of Herchel's life is now presented by Professor Edward S. Holden, in a charming little book which may be read at a single sitting, and yet complete and ample in all the details necessary to convey to the reader a vivid picture of the great Astronomer.

We admire Professor Holden's book for its simplicity of diction; not a superfluous word is given, and most of the more interesting events are given in the very words of his sister as recorded by her.

We desire to see this interesting work in the hands of the youth of this country, for if a noble example of a successful career will stimulate a young man to exalted aspirations for a useful and honorable life, the perusal of the present memoir should have such an inspiring effect.

We acknowledge the receipt of the following important works from the Government of New Zealand, being part of a series prepared by the Colonial Museum and Geological Survey Department, of which James Hector, M. D., C. M. G., F. R. S., is Director in Chief:

A MANUAL OF THE NEW ZEALAND MOLLUSCA.—A systematic and descriptive catalogue of the marine and land shells, and of the soft Mollusks and Polyzoa of New Zealand and the adjacent islands, by Frederick W. Hutton, F. G. S., C. M. Z. C., Professor of Biology, Canterbury College, New Zealand University, Wellington, 1880.

A MANUAL OF THE NEW ZEALAND COLEOPTERA, by Captain Thomas Brown, Wellington, 1880.

This Catalogue occupies 650 pages and contains 1050 species. It is a complete description of all the New Zealand Coleoptera known to Science, classified according to the views of Lacordaire. This valuable work is spoken of as a monument to the zeal and industry of an ardent naturalist.

PALÆONTOLOGY OF NEW ZEALAND.—Part IV.—Corals and Bryozoa of the Neozoic period in New Zealand; by the Rev. J. E. Tenison-woods, F. G. S., F. L. S. Wellington, 1880.

The author has a high reputation for his minute acquaintance with the Marine Invertebrata of the tropical and temperate parts of Australia, and during the last twenty years has published many works on the subject, so that the inferences drawn in this work may be received with much confidence.

MANUAL OF THE INDIGENOUS GRASSES OF NEW ZEALAND, by John Buchanan, F. L. S., Land-Botanist and Draughtsman of the Geological Survey. Wellington, 1880.

The general system of classification employed by the author is that adopted from Sir Joseph Hooker's standard works on the New Zealand Flora, but the methods upon which the general and specific characters have been arranged is from a more recent work on the British Flora by the same distinguished botanist. Sixty full-page illustrations are given of specimens, nature-printed, each having, in addition, from 10 to 25 drawings showing the anatomical character of the inflorescence in each species, from original microscopic dissections made by the author, whose excellent botanical knowledge, combined with his skill as a draughtsman, peculiarly fitted him for the work.

TRANSACTIONS AND PROCEEDINGS OF THE NEW ZEALAND INSTITUTE, 1879.,Vol.VII., edited by James Hector, C. M. G., M. D., F. R. S.; issued May, 1880. Wellington.

In this volume is a valuable series of papers, many of them well illustrated, and we congratulate the colony on the valuable scientific work accomplished and in progress. We find many of the papers in this volume of the highest interest, and we shall shortly present our readers with selections.

Any of our readers residing in New York who desire to examine these works can do so by calling at our office, and it may be convenient to know that the Colonial Government has arranged a scale of moderate charges, at which any of these publications can be purchased.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

P. O. Box 3838

SATURDAY, MARCH 26, 1881.

ANATOMICAL NOMENCLATURE.

In this and in the preceding number considerable space is devoted to a somewhat elaborate discussion of the general subject of Anatomical Nomenclature, accompanied by practical suggestions with regard to the brain.

When we consider that, as stated by Professor Wilder, the brain presents about 150 parts or regions which are visible to the unaided eye, that these parts are more and more frequently mentioned in connection with the progressive sciences of Anatomy, Zoology, Physiology and Psychology, and yet that many of them have received from two to a dozen, more or less, ponderous names, there would seem to be no question as to the desirability of some improvement upon the existing terminology.

The author of this article has undertaken to amend the matter by selecting the shortest or otherwise most appropriate one of the several names by which some parts are known, or by abbreviating descriptive phrases either by discarding all but the most significant word, or converting qualifying adjectives into prefixes, or, in a few cases, mostly of parts observed by himself, by proposing new terms altogether.

The fact is, as every original investigator is aware, all scientific nomenclature is more or less provisional, and must be constantly modified to suit the additions to knowledge and the clearing-up of ideas. The author has given a few instances of the employment of new terms by modern writers, and many more might have been adduced. Marsh uses "postpubis," Huxley "epipubes, pylangium, synangium, intraovular;" Foster employs—if he did not originate—"hemisection and aspychical;" "orad" is used by Thacher in place of *cephalad*, while "dorsad" occurs in recent writings of Mivart, and in Huxley's latest utterance, the paper on "Evolution," parts of which were reprinted in this journal.

Among all the arguments in favor of some modification of the existing nomenclature, the strongest—to the mind of the unprejudiced layman—is, perhaps, the very one which will least commend itself to the professional anatomist: namely, that the ease and comfort of those now living should be held of little moment as compared with any advantage which the change may confer upon the "vastly more numerous anatomical workers of the future."

Those who object to the strictly technical construction of the proposed vocabulary should try to realize what would be the outcome of a total disuse of all technical terms, and the substitution therefor of the vernacular words which are current among the people of the various countries in which anatomy is cultivated. Ancient Babylon would have a parallel in modern Science, and there would result confusion, misunderstanding, contention, and finally apathy and ignorance. Professor Wilder has evidently prepared his article in the hope of eliciting criticism from the working-anatomists of all parts of the world, and not with a view to the hasty praise or dissent of English-speakers alone.

The pages of "SCIENCE" are open to the fullest and freest discussion of the whole subject.

A PARTIAL REVISION OF ANATOMICAL NOMENCLATURE, WITH ESPECIAL REFERENCE TO THAT OF THE BRAIN.*

By BURT G. WILDER, M.D.,

Professor of Comparative Anatomy, etc., in Cornell University, and of Physiology in the Medical School of Maine.

II.

GENERAL NAMES OF ORGANS, AND THEIR ABBREVIATIONS.

For ease of reference these words are arranged in the alphabetical order of their abbreviations.

A.—Area. Ar.—Arteria. Ath.—Arthron, joint, articulation. B.—Bulbus. C.—Cœlia; ventricle of the brain. Cd.—Condylus. Co.—Columna. Cn.—Canalis. Cp.—Corpus. Crn.—Corona. Cr.—Crus. Cs.—Commissura. Ctl.—Cartilago. Dg.—Digitus, finger or thumb. Dm.—Dimidium; half. Dt.—Dactylus; toe, digitus pedis. Dv.—Divisio. F.—Fissura. Fm.—Foramen. Fs.—Fossa. Fsc.—Fascia. Gl.—Glandula. G.—Gyrus; convolution. L.—Lobus. Lc.—Locus. Lg.—Ligamentum. Ll.—Lobulus. Ln.—Linea. M.—Musculus. Mb.—Membrana. Math.—Mesarthron; segment. N.—Nervus. O.—Os. P.—Portio. Pl.—Plexus. R.—Recessus. Rg.—Regio. Rm.—Ramus. Rx.—Radix; root. S.—Sinus. Sb.—Substantia. Sl.—Sulcus. Sp.—Spina. Spt.—Septum. T.—Tuber. Tu.—Tuberositas. Tbl.—Tuberculum. Tr.—Tractus. V.—Vena.

LIST OF NAMES OF PARTS OR FEATURES OF THE BRAIN.

This list includes between 150 and 160 names. Unless otherwise stated they apply to the brains of Man and the Domestic Cat. Most of the names refer to more

* Continued from No. 38, page 126, March 19, 1881.

or less distinct parts, but a few indicate general regions, or areas which are distinguishable by color or elevation. No purely histological features are referred to. Some parts of the cerebellum and medulla are omitted altogether. The names of the fissures of the cat's cerebrum have been discussed in a previous paper, 8.

In each case, the name first given is regarded as preferable; but occasionally I have indicated the desirability of a better one. So much of each name as is printed in small capitals is regarded as a sufficient designation of the part under ordinary circumstances; sometimes it may be desirable to add the words in parenthesis. Most of the names are those in common use, with the omission of superfluous elements like *corpus*, and the genitives of the names of more comprehensive parts. Most of the apparently new names will be found to be old acquaintances under such thin disguises as *translation, transposition, abridgement*, and the *substitution of prefixes* for qualifying words. In a few cases the old names are wholly discarded for briefer new ones. Most of the new names, however, refer to parts apparently unobserved hitherto (*e. g., crista, carina, delta,*) or to parts which—although probably observed—seem not to have been regarded as needing a special designation, (*e. g., aula, quadrans, corpus præpontile.*)

Let me express here my desire to be favored with the fullest and freest criticism, both as to the general questions involved in this revision, and as to the special terms here proposed.

ALBICANS, (Corpus).—*abn.*—C. *candicans, c. mammillare*, etc. Unable to ascertain which of its many titles has priority, I select that which indicates its most obvious feature on the fresh brain.

AMYGDALA, (cerebelli).—*ag. cbl.*

ARACHNOIDEA, (Membrana).—*Ach.*—The arachnoid layer.

AREA CRURALIS.—*Ar. cr.*—The general region of the base of the brain between the pons and the chiasma. The middle region, or region of the isthmus.

AREA ELLIPTICA.—*A. el.*—An area, in the cat, just laterad of the ventripyramis. Perhaps it represents the "inferior olive."

AREA INTERCRURALIS.—*Ar. icr.*—The interpeduncular space. The mesal part of the *Area cruralis.*

AREA POSTPONTILIS.—*Ar. ppn.*—The ventral aspect of the metencephalon, (medulla). The caudal one of the three general regions into which the base of the brain may be conveniently divided for description. It is more extensive, relatively, in the cat than in man.

It will be noted that the adjective *pontilis* follows the analogy of *gentilis* rather than *montanus* or *fontinalis*. The form *pontal*, however, has been used by Owen. (A, III).

AREA PRÆCHIASMATICA.—*Ar. prch.*—The cephalic one of the three areas of the base of the brain. The space cephalad of the chiasma.

ARBOR VITÆ (cerebelli).—*Arb.*

AULA.—*a.*—The cephalic portion of the third ventricle; the prethalamic part of the "third ventricle," between the two portæ, or *foramina Monroi*; 'aula,' Wilder, 3 and 5." "The here common ventricular cavity," in *Menobranchus*, Spitzka, 6, 31. This represents the cavity of the "unpaired hemisphere vesicle," formed by a protrusion from, or constriction of, the "anterior primary encephalic vesicle," the aula is relatively larger in some of the lower vertebrates.

AULIPLEXUS.—*apx.*—The plexus of the *aula*. The free border of the fold of *pia*, known as the *velum*, forms a vascular plexus in the *aula*, in each *porta*, and in the *medicornu* of the *procœlia*. In place of compound terms, like *plexus aulæ*, etc., I suggest that single terms be formed, *auliplexus, portiplexus*, and *proplexus*. For the plexuses of the diacœlia and metacœlia—the "third" and "fourth ventricles"—we may use *diplexus* and *metaplexus.*

BASICOMMISSURA.—*bcs.* "The basilar commissure of the thalami," Spitzka, 2, 14. The ventral continuity of the two thalami.

BIVENTER (cerebelli).—*bv.*—The biventral lobe of the cerebellum.

BULBUS OLFACTORIUS.—*B. ol.* The olfactory bulb. The more or less expanded cephalic part of each lateral half of the rhinencephalon, consisting of the *pes* and *pero*. Often called *olfactory lobe.*

CALAMUS (scriptorius).—*clm.*

CALCAR (avis).—*clc.* *Hypocampa*, or *hippocampus minor.*

CALLOSUM, (corpus).—*cl.*—*Commissura cerebri maxima, trabs medullaris*, etc.

CANALIS CENTRALIS (myelonis).—*Cn.ce.*—The central canal of the spinal cord.

CARINA (fornicis).—*ca.*—The mesal ridge of the caudo-ventral surface of the *fornix*, dorso-caudad of the *crista*. I am not sure of its existence in man.

CAUDA STRIATI.—*cd. s.*—"Surcingle," Dalton (1, 13); the slender continuation of the *striatum* caudo-ventrad. If a new name is required for this longer "tail," which was described by Cuvier (B. 111, 51), as forming, with the striatum proper, a "horse-shoe," Prof. Dalton's "surcingle" may be technically rendered "cingulum." I have not yet looked for the *cauda* in the cat.

CEREBELLUM.—*cbl.*—Several of the external features of the *cerebellum* are omitted from this paper.

CEREBRUM.—*cb.*—The *prosencephalon*, less the *striata*. The *hemisphæræ.*

CHIASMA (opticum, or nervorum opticorum).—*ch.*—The optic chiasma or commissure.

CIMBIA.—*cmb.*—"*Tractus transversus pedunculi*," Gudden, as quoted by Meynert (A, 737). A slender white band across the ventral surface of the *crus cerebri*. It is a distinct ridge in the cat. The word is used in architecture to denote a *band* or *fillet* about a pillar, and is here proposed as a fitting substitute for Gudden's descriptive name.

CINEREA, (substantia).—*c.*—The gray matter of the nervous organs.

CLAUSTRUM.—*cls.*—The "*claustrum*," (Burdach); "*nucleus tæniæformis*," (Arnold), as stated by Quain, A. II, 564.

COLUMNA (fornicis).—*Co. f.*—The anterior pillar of the fornix, assuming that there is one upon each side. It would be convenient to have a single short name.

CŒLIA.—*C.*—A ventricle of the *encephalon*. For a brief statement of the reasons for substituting this for the word *ventriculus*, see elsewhere in this article.

COMMISSURA FORNICIS.—*Cs. f.*—In the cat, a distinct band across the caudal aspect of the *fornix* just ventrad of the *crista*, and apparently uniting the two columnæ more closely.

COMMISSURA HABENARUM.—*cs. h.*—A white band connecting the caudal ends of the habenæ, and forming the dorsal border of the *Fm. conarii.*

CONARIUM.—*cn.*—The *glandula pinealis. Epiphysis cerebri. Penis cerebri.*

CORONA RADIATA.—*Cn. r.*—*C. radians.*

CORPUS PRÆPONTILE.—*Cp. prp.*—A slight white longitudinal ridge of the *postperforatus*, near the meson. It is distinct in the cat. When more fully known, perhaps a better name may be found.

CORTEX (cerebri, or cerebelli).—*ctx.*—The ectal layer of gray and white substance at the surface of the cerebrum and cerebellum.

CRENA (calami).—*crn.*—The caudal end or notch of the metacœlia.

CRISTA (fornicis).—*crs.*—A small but, in the cat, very distinct ovoid mesal elevation of the caudal surface of the *fornix*, ventrad of the *carina*, and dorsad of the *commissura fornicis*, and the *recessus aulæ*. It is also present in the human brain. Wilder, 7.

CRUS CEREBRI.—*Cr. cb.*—Pedunculus cerebri.

CRUS OLFACTORIUM.—*Cr. ol.*—The isthmus by which the *bulbus olf.* is connected with the *prosen.*

CRUSTA (cruris cerebri). *cst.*

DECUSSATIO PINIFORMIS.—*dc. pnf.*—"Piniform decussation," Spitzka.

DECUSSATIO VENTRIPYRAMIDUM.—*dc. vpy.*—The "decussation of the anterior pyramids."

DELTA (fornicis).—*d.*—A subtriangular area of the ventro-caudal surface of the fornix of the cat. The lateral angles are at the *portæ*, and the apex points dorso-caudad. It is bounded by the lines of reflection of the *endyma*, and represents the entocœlian surface of the *fornix*. Wilder, 5. It probably exists in man.

DENTATUM, (corpus cerebelli).—*dnt.*

DISTELA.—*dtl.*—The *tela vasculosa* forming the membraneous roof of the *diccelia* or "third ventricle."

DIENCEPHALON. — *den.* — The *thalamencephalon, deutencephalon, inter-brain*, enclosing the *diccelia*. Whether it should include also the *aula* and its walls is to be determined by reference to the condition of the parts in some of the lower vertebrates.

DORSIPYRAMIS.—*dpy.*—The *posterior pyramid* of the *metencephalon.*

DICŒLIA.—*dc.*—The "third ventricle," or "*ventriculus tertius*," less the *aula*. The interthalamic space, reduced in mammals by the *medicommissura.*

DIPLEXUS.—*dpl.*—The plexus of the "third ventricle."

ENCEPHALON.—*en.*—The brain, including the *medulla* or *metencephalon.*

ENDYMA.—*end.*—*Ependyma.* Lining membrane of the ventricles.

EPENCEPHALON.—*epen.*—The hind-brain, or *cerebellum* with the *pons* and its peduncles, and the corresponding part of the *medulla*. It is difficult, perhaps impossible, to define exactly the limits of the epen. and the metencephalon, and of their respective cavities.

EPICŒLIA.—*epc.*—The division of the ventricular cavity corresponding with the cerebellum. Perfectly disinct in the cat, and even in man, but relatively more extensive in many of the lower vertebrates.

FASCIOLA.—*fscl.*—May not this single word take the place of *fasciola cinerea* and *fascia dentata?* The parts are continuous, and the latter is not *dentate* in the cat.

FILUM TERMINALE (myelonis).—*fl. t.*

FIMBRIA.—*fmb.*—*Corpus fimbriatum. Tænia hippocampi.* "*Fimbria*," Meyn. A, 667.

FLOCCULUS.—*flc.*—*Lobulus pneumogastricus.* The flocks. This seems to be a different part from the *lobulus appendicularis* of the carnivora, with which it has been sometimes confounded.

FORAMEN CÆCUM.—*Fm. c.*—"*Fossa cæca*," Spitzka, 3, 6. *Foramen cæcum* is used by Dunglison and Vicq D'Azyr (A, pl. xviii., "48"), and should be retained, notwithstanding the somewhat unusual application of the word *foramen.*

FORAMEN INFUNDIBULI.—*Fm. inf.*—The orifice in the *tuber cinereum* left after the removal of the *hypophysis* and *infundibulum.*

FORAMEN MAGENDIE.—*Fm. mg.*—The communication of the *metacœlia* with the "subarachnoid space." Not having satisfied myself as to the nature of this communication, I prefer to quote from Quain, A, ii., 513.

FORNIX.—*f.*—*Camara. Testudo cerebri*, &c.

GENU.—*g.*—*Genu callosi.*

HABENA. — *h.* — *Habenula. Pedunculus pinealis.* There seems to be no need of using the longer word. According to my observations, the *habenæ* have a distinct morphical significance as nearly corresponding with the lines along which the *endyma* is reflected toward the opposite side; 5 and 7.

HYPOPHYSIS.—*hy.*—Pituitary body.

HYPOCAMPA.—*hym.*—*Hyppocampus major.* The reasons for preferring the form employed by Vicq D'Azyr are presented elsewhere in this article.

ITER.—*i.*—*Iter a tertio ad ventriculum quartum. Aquæductus Sylvii.* A convenient name for the contracted mesocœlia of man and most mammals.

INSULA.—*ins.*—Island of Reil. *Lobus centralis. Insula cerebri. Gyri operti.*

INFUNDIBULUM.—*inf.*—*Infundibulum cerebri*, &c.

INTEROPTICUS.—(*lobus*).—*iop.*—The interoptic lobe; Spitzka, 4, 98; 5. In some reptiles.

LEMNISCUS INFERIOR.—*lmn. i.*—Spitzka, 4, 95 and 100.

LEMNISCUS SUPERIOR.—*lmn. s.*—I have not been able to identify these parts in the cat.

LIGULA.—*lg.*—"Ponticulus." Ligula, Quain, A, 11, 506.

LIMES ALBA.—*lm. a.*—*Limes alba radicis lateralis rhinencephali.* The white stripe of the lateral root of the rhinencephalon. Perfectly distinct in the fresh brain of the cat.

LIMES CINEREA.—*lm. c.*—The gray stripe of the radix lateralis.

LIQUOR VENTRICULI.—*lq. vn.*—This term is used by Mihalk. A, 163. Is a better one to be found?

LOBULUS APPENDICULARIS (cerebelli). *Ll. ap.* The appendicular lobule of the *cerebellum* of many carnivora, and perhaps other mammals. It seems to have been confounded in some cases with the human *flocculus*, but more probably represents the lateral lobes of the cerebellum. Its relations should be studied in a series of related forms. See my paper, 11, 217.

LOBULUS OLFACTORIUS.—*L. ol.* — The olfactory lobe of the hemisphere. A part of the hemisphere said to be in more direct connection with the rhinencephalon.

LOBUS OLFACTORIUS.—*L. ol.*—A general name for either half of the rhinencephalon, including the crus and the bulbus.

LOCUS NIGER.—*lc. n.*—The *locus niger* of the *crus cerebri*, between the *tegmentum* and the *crusta.*

MEDICOMMISSURA.—*mcs.*—*Commissura mollis.* Middle commissure. "Thalamic fusion," Spitzka.

MEDICORNU (procœliæ).—*mcu.*—*Cornu temporale.* The middle or descending horn of the "lateral ventricle."

MEDIPEDUNCULUS (cerebelli).—*mpd.*—*Crus ad pontem.* Middle peduncle of the cerebellum.

MESENCEPHALON.—*men.*—The mid-brain. The *lobi optici, postoptici and interoptici*, with the corresponding *crura cerebri.*

MESOCŒLIA.—*msc.* The ventricular division corresponding with the *mesencephalon*. In man and most mammals it is usually reduced and known as *iter*, or *aquæductus Sylvii.*

METATELA.—*mtl.*—The membraneous roof of the *metacœlia*, or "fourth ventricle."

METACŒLIA.—*mtc.*—The "fourth ventricle," *ventriculus quartus.* Ventricle of the metencephalon.

METAPLEXUS.—*mtpl.*—The *plexus choroideus* of the *metacœlia.*

MONTICULUS (cerebri).—*mnt.*—The ventral prominence of the *lobus temporalis.* Natiform protuberance. *Alveus. Subiculum.*

MYELENCEPHALON.—*myen.*—The cerebro-spinal axis. The term was proposed by Owen.

MYELON.—*my.*—The spinal cord. Owen. Huxley.

NERVUS OLFACTORIUS.—*N. ol.*—Olfactory nerve.

NUCLEUS LENTICULARIS.—*nc.ln.*—*Nucleus lentiformis.* Meynert.

OBEX.—I have not identified this part.

OLIVA.—*o.*—*corpus olivarium.* Olivary body. Olive. The "inferior olive." Spitzka.

OPTICUS, (lobus). *Natis cerebri.* An optic lobe, excluding the *postopticus and interopticus.*

PERO (olfactorius).—*po.*—The softer cap, or shoe-like covering of the rhinencephalic lobe, from which the *nervi olfactorii* directly spring. In the cat this may be accurate-

ly removed from the *pes ol.* The Latin *pero* denoted a sort of boot made of raw hide.

PES OLFACTORIUS.—*ps. ol.*—The firmer ental portion of each rhinencephalic lobe. As it is the termination of the crus, and has, in the cat, a somewhat foot-like shape, I suggest the above name for it.

PIA (mater).—*pi*— In the cat's brain there are indications of at least two layers of the *pia.*

PONS (Varolii).—*pn.*—*Tuber annulare,* etc. There seems to be no need of the qualifying genitive.

PONTIBRACHIUM.—*pnbr.*—"*brachium pontis;*" Spitzka, 4, 100.

PORTIO DEPRESSA (præperforati).—*Pt. d.*—In the cat the (*locus*) *præperforatus* is distinctly divided into two portions, the caudal of which is depressed, while the cephalic is elevated, and sometimes furrowed. Briefer names are desirable.

PORTIO PROMINENS (præperforati).—*Pt. p.*

POSTBRACHIUM (mesen.).—*pbr.*—*Brachium posterius.*

PRÆBRACHIUM (mesen.).—*prbr.*—*Brachium anterius.* I have not identified these parts.

PORTIPLEXUS,—*ppl.*—The small portion of the free border of the *velum* which hangs in the *porta.*

POSTCOMMISSURA.—*pcs.*—*Commissura posterior cerebri.* The posterior commissure.

PRÆCOMMISSURA.—*prcs.*—*Commissura anterior.*

POSTGENICULATUM, (corpus).—*pgn.*—*Corpus geniculatum internum.*

PRÆGENICULATUM, (corpus).—*prgn.*—*corpus geniculatum externum.*

POSTOPTICUS, (lobus).—*pop.*—*Testis cerebri.* The caudal eminence of the "*corpus quadrigeminum.*" "Postoptic lobe," Spitzka, 4, 100, and 103.

POSTPEDUNCULUS (cerebelli).—*ppd.*—*Crus cerebelli ad medullam.* Inferior peduncle.

PRÆPEDUNCULUS.—*prpd.*—*Crus seu processus ad corpus quadrigeminum.* Superior peduncle of cerebellum.

POSTPERFORATUS, (locus).—*ppf.*—*Locus perforatus posticus.* Posterior perforated space. *Pons Tarini.*

PRÆPERFORATUS.—*prpf.* *Locus perf. anticus.*

PROCŒLIA.—*prc.*—Ventricle of the prosencephalon, "Lateral ventricle."

PROPLEXUS.—*prp.*—The plexus of the *medicornu* of the *procœlia.* It is the long free border of the *velum,* and, still covered by the *endyma,* enters by the rima. It is continuous with the *portiplexus,* and extends to near the tip of the *medicornu.*

PROSENCEPHALON.—*pren.*—The cerebral hemispheres ; *cerebrum* less the *striatum* ; the fore-brain.

PROTERMA.—*prtr.*—The primitive *lamina terminalis* or *l. cinerea.* *Terma embryonis.* My reason for suggesting different terms for the adult and embryonic terminal plate, is that, as now understood, the latter includes not only the *lamina cinerea* of anthropotomy, but also the parts afterward differentiated to form the *columnæ fornicis,* and the *præcommissura,* with perhaps some other parts of the *fornix.*

PSEUDOCŒLIA.—*psc.*—*Ventriculus septi pellucidi.* "Duncan's höhle," Lœwe, A, 13. Fifth ventricle. This is not a true member of the cœlian series. If it ever presented an opening into the *aula,* it is because of some injury which has torn the brain. This point was urged by me in the unpublished paper No. 4.

PULVINAR.—*plv.*—*Pulvinar thalami.* The posterior tubercle of the human *thalamus.*

QUADRANS, (cruris cerebri).—*q.*—In the cat, a depressed area approximately equal to the fourth of a circle, upon the ventral surface of the *crus,* in its meso-cephalic angle.

RADIX INTERMEDIA (rhinencephali).—*Rx.* I.—The middle root of the *rhinencephalon.* In anthropotomy, the *middle* root of the olfactory nerve. In the cat it is little more than a sub-triangular interval between the RR. *lateralis* and *mesalis.*

RADIX MESALIS.—*Rx. m.*—The mesal root of the *rhinencephalon.* The "internal root of the olf. nerve." In the cat, it turns pretty sharply from the ventral to the mesal aspect of the brain.

RADIX LATERALIS.—*Rx. l.*—The lateral root of the *rhinen.* The "external root of the olf. nerve." In the cat it presents a gray and a white stripe—*limes cinerea* and *l. alba.*

RECESSUS AULÆ.—*R. a.*—A small depression between the two *columnæ fornicis,* and ventrad of the *crista.* The aulic recess.

RECESSUS CONARII.—*R. cn.*—"*Recessus pinealis,*" Reich. A, Taf. ix, *rp.*

RECESSUS OPTICUS.—*R. op.*—This is a pyramidal recess, just dorsad of the *chiasma,* the apex pointing laterad. The term is used by Mihalkovics, A, 79.

RECESSUS PRÆPONTILIS.—*R. prpn.*—The mesal depression which is overhung by the cephalic border of the *pons.* Its floor is formed by the caudal part of the *postperforatus.*

REGIO AULICA.—*Rg. a.*—It may be convenient sometimes to employ this term as a designation for the general region, of which the *aula* is the center. Within a short distance of the *aula* are many parts of great morphical importance ; the whole brain seems to converge thereto. Whoever understands the aulic region will find no serious difficulty with the gross anatomy of other parts.

RESTIFORME, (corpus).—*Rf.*—The restiform body of the *metencephalon.*

RHINENCEPHALON.—*rhen.*—The division of the brain, which is united with the cephalic end of the base of the *prosencephalon,* and connected by the *nervi olfactorii* with the *nares.* Each lateral *lobus* includes a *crus* with its *radices,* and the *bulbus olfactorius,* consisting of the *pes* and *pero.*

RHINOCŒLIA.—*rhc.*—The cavity or ventricle of each lateral part of the *rhinencephalon,* and connected with the procœlia.

RIMA (cerebri). *r.* The interruption of nervous tissue between the *fimbria* and the *tænia,* by which the fold of *pia*—still covered by the *endyma*—enters the *procœlia* to form the *proplexus.*

It extends from the dorsal border of the corresponding *porta* to near the tip of the *medicornu.* In a general way it coincides with a lateral half of the "fissure of Bichat," or "great transverse fissure." That, in the cat, the borders of this *rima* are closely united by the intruded *pia,* and that the *thalamus* is *wholly excluded from the procœlia,* was demonstrated by me on the 25th of November, 187-, in the presence of my assistant, Prof. S. H. Gage, who recorded it at the time. It was affirmed in my lectures on Physiology at the Medical School of Maine in the Spring of 1877, and in subsequent courses there and at Cornell University ; and was one of the points made in a paper (4) read at the meeting of the Am. Assoc. Adv. of Sci. in 1879. While affirming this of the cat, I stated that the material at my disposal had not enabled me to demonstrate it upon the human brain, but there was no doubt that the same condition would be ascertained when a human brain could be prepared and examined with sufficient care with reference to that feature. In the Spring of 1880, Dr. Spitzka informed me that Hadlich had denied lately the appearance of the *thalamus* in the lateral ventricle, presumably of man. The fact is, whoever begins his studies of encephalic anatomy with the brains of the lower vertebrates will soon perceive that—excepting for some rupture of the parts—the *thalamus* can no more form a part of the floor of the "lateral ventricle" than can the *cerebellum* or any other part of the brain.

RIPA (deltæ).—*rp.*—The border of the *delta* formed by the reflection of the *endyma* upon the intruded *auliplexus.* Probably also in man.

ROSTRUM (callosi).—*rm.*—The rostrum of the *callosum ;* much shorter in the cat than in man.

SEPTUM LUCIDUM,—*spt. l.*—This term is not only compound, but based upon two misconceptions: that it

is always or even usually *translucent* in mammals, and that it forms a partition between the two *procœliæ* in the ordinary sense. A new term is desirable, which may refer to either of the two lateral halves of the septum, in connection with the *procœlia*, or the rest of the wall of the hemisphere.

SPLENIUM (callosi).—*sp* —The splenium.

STRIATUM, (corpus).—*s.*—The intraventricular, or entocœlian, portion of what is sometimes called the *corpus striatum*. The *nucleus caudatus*. The caudate lobe.

SULCUS HABENÆ.—*Sl. h.*—The slight furrow along the dorsal border of the *habena*.

SULCUS INTERCRURALIS LATERALIS.—*Sl. ic. l.*—In the cat, a distinct lateral furrow in the *area intercruralis*.

SULCUS INTERCRURALIS MESALIS.—*Sl. ic. m.*—A mesal furrow in the *area intercruralis of the cat*.

SULCUS LIMITANS.—*Sl. li.*—The furrow between the *thalamus* and *striatum*, in which lies the free border of the *fimbria* in contact with the *tænia*. The qualifying word is given in reference to the fact that this furrow is the line of separation between the entocœlian surface of the *striatum* and the ectocœlian surface of the *thalamus*. A shorter and more significant term is desirable.

SULCUS MONROI.—*Sl. Mn.*—The term is employed by Reichert, (A, 65, Taf. 11), to designate a part of the *dicœlia* of man ventrad of the *medicommissura*.

TÆNIA (semicircularis).—*tn.*—There seems to be no reason why this single word may not replace the numerous compounds by which the part is known.

TEGMENTUM.—*tg.*—The more dorsal layer of fibers of the *crus cerebri*, separated from the *crusta* by the *locus niger*.

TELA.—*tl.*—A general name for the membraneous roofs of the *dicœlia* and *metacœlia*. "*Tela vasculosa*" is employed by Huxley, *I.*

TERMA.—*tr.*—*Lamina cinerea*. The adult *lamina terminalis*.

THALAMUS.—*th.*—*Thalamus opticus* seu *nervorum opticorum*. As has been well remarked by Spitzka (2), this single word is to be preferred upon all grounds to the compounds which have been applied to this part.

TRACTUS OPTICUS.—*tr. op.*—The optic tract.

TRAPEZIUM.—*tz.*—The *trapezium* of the *metencephalon*. Exposed in the carnivora, but in man concealed by the caudal margin of the *pons*.

TUBER CINEREUM.—*T. cn.*—The elevation just caudad of the *chiasma*, to which is attached the *hypophysis* by the *infundibulum*.

TUBERCULUM ROLANDO.—*tbl. R.* The tubercle or tuber of Rolando, Huguenin, A, 83.

VALVULA (cerebelli).—*vv.*—The valve of Vieussens.

VELUM (interpositum).—*vl.*—The ectocœlian portion of the fold of *pia*, the entocœlian free border of which forms the plexuses of the aula, portæ, and procœliæ.

VENA CHOROIDEA.—*v. ch.*—*Vena Galeni.*

VENTRIPYRAMIS.—*vpy.*—The anterior pyramid. The "prepyramid," Owen, A.

VERMIS (cerebelli).—*vm.*—The median lobe of the cerebellum. This and the other external features of the cerebellum are not here presented with any fullness.

If I venture to hope that a few of the changes proposed in this paper may escape disapprobation, and that all my readers may not be hostile critics, it is because the times have changed, and such an undertaking is now more likely to be viewed in its true light. I have endeavored simply to define more clearly the necessity for terminological improvement which has been admitted, in some cases unconsciously perhaps, by all who have, for example, substituted *ventral* for *anterior*, *ectoglutæus* for *glutæus maximus*, *hypophysis* for *pituitary gland*, *corpus callosum* for *commissura cerebri maxima*, *adrenals* for *suprarenal capsules*, and *basioccipital* for *basilar portion of the occipital bone.*

In evidence that the suggestions here made are not impracticable, it may be proper to state that most of the terms enumerated, particularly those of toponomy, have been used in the anatomical laboratory of Cornell University for from one to three years; that the freest criticism has been asked from the score or two of students working at practical anatomy and making their own descriptions under the immediate direction of Professor Gage; and that, so far from there having been any inconvenience, the wish has been expressed that a similar terminology might be adopted elsewhere.

On what may be called experimental grounds, therefore, it seems to me that, whatever may befall the particular terms here presented, as biological knowledge is more widely diffused, and the demand for it correspondingly increased, considerable changes in nomenclature must be effected unless anatomical teachers are willing to be styled professors of the art of needless mystification.

There is, however, little danger of the too rapid progress of terminological reform; for, whatever may be the general pressure of students and the public, definite innovations are rarely made without the sanction, or at least the toleration, of those who are most inconvenienced by any departures from custom.

The beginner can learn the new terms even more easily than the old, and at any rate he has nothing to forget. But the trained anatomist shrinks from an unfamiliar word as from an unworn boot; the trials of his own pupilage are but vaguely remembered; each day there seems more to be done, and less time in which to do it; nor is it to be expected that he will be attracted spontaneously toward the consideration that his own personal convenience and preferences, and even those of all his distinguished contemporaries, should be held of little moment as compared with the advantages which reform may insure to the vastly more numerous anatomical workers of the future.

THE BASIN OF THE GULF OF MEXICO.

By J. E. HILGARD, M. N. A. S.

A COMMUNICATION TO THE NATIONAL ACADEMY OF SCIENCES MADE NOV. 18, 1880, BY AUTHORITY OF C. P. PATTERSON, SUPT. U. S COAST AND GEODETIC SURVEY.

At the meeting of the National Academy of Sciences in New York, Nov. 18th, 1880, Mr. J. E. Hilgard presented, on the part of Hon. C. P. Patterson, Superintendent of the U. S. Coast and Geodetic Survey, a model of the Gulf of Mexico constructed from numerous soundings taken in the progress of that work. The accompanying plate is a reduced plan of the model, the full size of which is 24×32 inches, being on a horizontal scale of 1 : 2,400,000, and on a vertical scale of 1 inch : 1000 fathoms; making the proportion of horizontal to vertical scales 1 : 33. The plan shows the horizontal curves of every 500 fathoms of depth, as well as the curves of 100 and 10 fathoms. The same curves are delineated on the model, the forms of which, however, are shaped in conformity with all the detail obtained from the soundings, those inside of 100 fathoms being quite numerous, varying according to the configuration and importance of the locality, while beyond the 100 fathom line, where the work pertains rather to physical geography than to navi-

gation, 1055 soundings were obtained, of which 355 are in depths greater than 1000 fathoms.

The object of the communication being merely to give a general description of the structural features of the basin of this great inland sea—the American Mediterranean—it is only necessary to mention here, that in connection with the soundings, temperatures were taken at various depths, and the organic life was explored by means of dredges. Everywhere below the depth of about 800 fathoms, the temperature was found to be between 39° and 40° F. The method of sounding was by the use of fine steel wire, indicated by Sir Wm. Thomson, with the mechanical appliances perfected by Commanders Belknap and Sigsbee of the U. S. Navy.

The exploration of the Gulf of Mexico was begun by the U. S. Coast Survey as long ago as 1846, when surveys of the shores were made, and soundings of the approacnes were obtained under the Superintendency of Prof. A. D. Bache. These investigations continued until the outbreak of the civil war, Prof. Bache having in view from the earliest date of his work, the exploration of the Gulf Stream and its attendant phenomena, in addition to the surveys requisite for navigation. When after the close of the war the Coast Survey resumed its former activity, under the administration of Prof. Benjamin Peirce, the physical and biological investigations were continued; but it was not until the present Superintendent of the U. S. Coast Survey, (C. P. Patterson, LL.D.) organized a systematic Exploration of the whole Gulf, that its character became rightly understood. These explorations, begun in 1872 by Commander Howell, U. S. N., on the west coast of Florida in comparatively shallow water, were continued and brought to a successful conclusion by Commander Sigsbee, U. S. N., (1875–78) in the steamer "Blake," accompanied by Prof. A. Agassiz in charge of biological investigations. The methods of obtaining temperatures at great depths as well as of dredging have been described in the Coast Survey Reports for several years past, and more especially in a treatise by Commander Sigsbee recently published by the Coast Survey.

Turning now to our model or map, we perceive that the basin of the Gulf of Mexico is an oval connected with the general ocean-circulation by two outlets, the Yucatan Channel and the Florida Straits. The area of the entire Gulf, cutting it off by a line from Cape Florida to Havana, is 595,000 square miles. Supposing the depth of the Gulf to be reduced by 100 fathoms, a surface would be laid bare amounting to 208,000 square miles, or rather more than one third of the whole area, The distance of the 100 fathom line from the coast is about 6 miles, near Cape Florida; 120 miles along the west coast of Florida; at the South Pass of the Mississippi, it is only 10 miles; opposite the Louisiana and Texas boundary, it increases to 130 miles; at Vera Cruz it is 15 miles, and the Yucatan banks have about the same width as the Florida banks.

The following table shows the area covered by the trough of the Gulf of Mexico to the depths stated:

Depth.	Area.	Differences.
2,000 fathoms	55,000 square miles	
1,500 "	187,000 "	132,000
1,000 "	260,000 "	73,000
500 "	326,000 "	66,000
100 "	387,000 "	61,000
Coast line	595,000 "	208,000

This table shows that the greatest slopes occur between the depths of 100 and 1500 fathoms. The maximum depth reached is at the foot of the Yucatan banks 2119 fathoms. From the 1500 fathom line on the northern side of the Gulf to the deepest water close to the Yucatan banks, say to the depth of 2000 fathoms, is a distance of 200 miles, which gives a slope of five-ninths to 200, and may be considered practically as a plane surface. The 2000 fathom area has received the name of "Sigsbee Deep," after its explorer. The Yucatan Channel with a depth of 1164 fathoms has a cross-section of 110 square miles while the Straits of Florida, in its shallowest part opposite Jubiter Inlet, with a depth of 344 fathoms has a cross-section of only 10 square miles.

A view of the model reveals at once some important facts which a study of the plan conveys but imperfectly to the mind, and which were unsuspected before the great exploration of the Gulf was completed.

Among the more striking features displayed by the model to which Mr. Hilgard called attention, were:

1. The great distance to which the general slope of the continent extends below the present sea level before steeper slopes are reached. The 100 fathom line represents very closely the general continental line. The *massifs* of the Peninsulas of Florida and Yucatan have more than twice their present apparent width.

2. Very steep slopes lead from this submerged continental plateau to an area as great as that of the State of Georgia at the enormous depth of over 12,000 feet. There are three ranges on the Florida and Yucatan slopes extending in the aggregate from five to six hundred miles, along which the descent from 500 to 1500 fathoms (or 6000 feet), is within a breadth of from six to fifteen miles. No such slopes and correspondingly elevated plateaus appear to occur on the un-submerged surface of the earth —the suggestion presents itself, that while the latter have suffered atmospheric erosion, those which we are considering have not sensibly changed from the positions assumed in the mechanical shaping of the earth's crust.

3. The far protrusion of the Mississipi Delta towards the deep water of the Gulf, seems to give evidence to the Engineer, of the probably permanent success of the Mississippi Jetties, as delivering the silt of the river into water of so great depth that but few extensions will ever become necessary. In connection with the same feature, the strong indentation to the westward of the present mouths of the Mississippi, indicating the probable site of the original fracture between the two slopes of the Mississipi Valley deserves attention.

4. In regard to the problem of general ocean circulation in connection with the Gulf Stream, the most important feature is the shallowness and small cross-section of the Straits of Florida between the Peninsular and Bahama banks, having at the shallowest part a cross-section of 11 square miles, with a greatest depth of 344 fathoms only. From observations published in the Coast Survey Reports the average northwardly current of the warm water through this Strait is probably not greater than 2 miles per hour—certainly not more than 2½ miles. It is evident, at once, that the warm water which so greatly modifies the climate of Western Europe, cannot all be supplied by the flow through this small channel. The concentration of the warm surface current from the Gulf of Mexico gives to this vein of the general circulation a marked velocity, which is not found in other portions of the Atlantic, and which, being perceptible to the navigator, has given its name of "Gulf Stream" to the whole system of the northeasterly surface-flow in the Atlantic Ocean. It is now necessary to assume that the so-called Gulf Stream is largely reinforced by a general northerly current from the outside of the West India Islands.

SCIENTIFIC SOCIETIES OF WASHINGTON.

THE BIOLOGICAL SOCIETY.—The Society met in the Smithsonian Institution, Friday evening, March 11th, President Gill in the Chair. The discussion was renewed upon Mr. True's paper respecting suctorial organs. Mr. Seaman spoke of certain plants, such as the American Woodbine, which seem to mimic the suctorial organs of animals. Professor Riley drew attention to the suctorial anal pseudopod of caterpillars, and Mr. Goode to the peculiar provision for prehension in

the marsupials. Dr. A. F. A. King read a paper on Septennial Periodicity, drawing attention to the phenomena of menstruation, œstration in animals, gestation, contagions, epidemics and climax of fevers. He was partially supported by Mr. Goode, who said that since the lunar month of four weeks had such an important bearing upon tides, etc., there is no absurdity in supposing that the same cause may have been at work through myriads of years to bring about periodicity as indicated in the paper. Professor Riley, Mr. Ward, the President, Dr. Prentiss, and others, took the opposite side of the question.

THE ANTHROPOLOGICAL SOCIETY.—Major J. W. Powell, the President, being in the Chair, the following papers were read : "Politico-Social Functions," Lester F. Ward ; "The Savage Mind in the presence of Civilization," by Otis T. Mason. Mr. Ward first drew attention to the schism which ever manifests itself between theory and practice. Political philosophy taught in the schools is one thing, political rules and maxims of society are quite another. The speaker criticised the interpretation of the old legal school of politics as well as the modern naturalistic school. The latter, in holding that nature's fixed laws cannot be violated, forgot to include in nature the struggles of human reason. This is well exemplified in the anecdote concerning Plato. When about to flog a slave for stealing, the latter thought to get off by crying, "It is my fate to steal." The philosopher quickly reminded the slave that it was also his fate to get thrashed for his theft. The paper took the ground that Society was tending more and more to protection, and, from a large collection of statistics showed that gradually new interests were passing under control of the State. Major Powell warmly endorsed Mr. Ward's remarks, and affirmed that the conviction had been growing upon him in favor of the following view : Society begins with the kinship tie, passes on to the property basis of organization, and culminates in the evolution and protection of industries. Mr. Mason's paper was partly theoretical and partly practical. Under the first head it was maintained that the conflicts of the human family in all time had brought the different races of men face to face with higher and better methods, and from these much aid had been received in their own advancement. The practical portion of the paper related to the education of our Indians. The speaker had gone over the history of the subject, had corresponded with every respectable school and college in the country, and had collected the statistics of government operations from the Indian Bureau. The conclusion arrived at was that much had been wasted through ignorance of anthropological methods, and that the organization of a Bureau of Ethnology had been the wisest scheme the government had undertaken in this regard.

MICROSCOPY.

We have received from Dr. William Hailes, of the Pathological Laboratory, Albany Medical College, specimens of injected preparations cut with his improved microtome, which was figured and described on page 187, vol. 1, of "SCIENCE." The sections are from the kidney of the cat, and are very perfect, showing the excellence of his microtome and his own methods of manipulation. Dr. Hailes also sends us three photographs of magnified specimens of the Embryo of the Chick, taken, respectively 24, 36, and 72 hours after commencement of incubation. These photographs are highly interesting, and may be seen at our office by those pursuing such studies.

Messrs. Lennis and Duncker, both of Berlin, have published an interesting paper in the Zeitschrift für Mikroskopische Fleischschau on a new parasite with which they have met while performing their official duty. In examining pork for trichinæ they discovered a vermicular *diatomea* imbedded between the muscular fibres which they describe in the following terms : It is exceedingly thin and transparent, of a greyish color, and of about the size of the cyst-wall of a trichina.

Professor Leuckardt is inclined to consider its presence in the pork as accidental, and believes that it is of little importance to government inspectors of meat in their official work.

A WRITER in *Nature* makes the following observations on the minute structure of metals hammered into thin leaves which are quite instructive. Notwithstanding the great opacity of metals it is quite possible to procure, by chemical means, metallic leaves sufficiently thin to examine beneath the microscope by transmitted light. Such an examination will show two principal types of structure, one essentially granular and the other fibrous. The granular metals, of which tin may be taken as an example, present the appearance of exceedingly minute grains, each one being perfectly isolated from its neighbors by still smaller interspaces. The cohesion of such leaves is very small.

The fibrous metals, on the other hand, such as silver and gold, have a very marked structure. Silver, especially, has the appearance of a mass of fine, elongated fibres, which are matted and interlaced in a manner which very much resembles hair. In gold this fibrous structure, although present, is far less marked. The influence of extreme pressure upon gold or silver seems to be, therefore, to develop a definite internal structure. Gold and silver, in fact appear to behave in some respects like plastic bodies. When forced to spread out in the direction of least resistance their molecules do not move uniformly, but neighboring molecules, having different velocities, glide over one another, causing a pronounced arrangement of particles in straight lines.

A new edition of Messrs. Beck's catalogue corrected to the first of this month has been received. It is a work of 176 pages, well illustrated and appears to cover all the wants of a microscopist. Mr. W. H. Walmsley, the manager of the American branch of this house, informs us that there is a large demand for microscopes at this time, and that orders are in advance of their means of producing instruments. We notice some change in the prices and that the "Economic" has been raised to $40 including objectives. Messrs. Beck & Co. have been very successful in producing good models for their microscopes, and their workmanship is excellent. Both Mr. Beck and Mr. Walmsley are accomplished microscopists, and can thus anticipate the requirements of their customers.

ASTRONOMY.

VARIABLE STARS OF SHORT PERIOD.*

Under the above title, Professor Pickering has read before the American Academy of Arts and Sciences, the second of two papers, both of which are to be regarded as preliminary, rather than final discussions, upon the causes of variability in the light of fixed stars. In the preceding paper (Proc. Amer. Acad. XVI., 1.) the following classification of variables was made:

I. Temporary stars. Examples, Tycho Brahe's star of 1572, new star in Corona 1866.

II. Stars undergoing slight changes according to laws as yet unknown. Examples o Ceti and χ Cygni.

III. Stars whose light is continually varying, but the changes are repeated with great regularity in a period not exceeding a few days. Examples, β Lyrae and δ Cephei.

IV. Stars which every few days undergo for a few hours a remarkable diminution in light, this phenomenon

* Proceedings of the American Academy of Arts and Sciences, Vol. XVI.

recurring with great regularity. Examples, β Persei and δ Cephei.

In order to avoid all prejudice, the present discussions are made to depend entirely on the work of previous observers, while awaiting the completion of more precise observations now in progress at Harvard College Observatory.

An investigation was given in the article referred to above, of stars of the fourth class. It was shown that in the case of β Persei at least, the observed variations could be very satisfactorily explained by the theory that the reduction in light was caused by a dark eclipsing satellite.

Variables of the third class are considered in the present paper. Perhaps the most natural supposition of the variability of a star of short period, is that it is due to rotation around its axis. The difference in brightness of the two sides of a star, which such an explanation demands, may be due to spots like those of our sun, to large dark patches, or to a difference in temperature. The theory that variation is due to the absorption of a rotating mass of gas, does not appear probable for stars of the third class, since no evidence of absorption is in general shown in their spectra, beyond the appearance of lines such as are seen in our sun. For the stars of the second class, however, this view seems more reasonable, since many of them exhibit spectra which are strongly banded.

"One great advantage of the study of the stars by physical instruments, as the spectroscope and photometer, is that some clew is given to certain laws, for our knowledge of which we must otherwise depend on theoretical considerations alone. While the conclusions to be drawn from micrometric measurements are, in general, much more precise, and the effects of the errors can be more certainly computed, they fail entirely to aid us in studying such laws as are here considered. For example, the present investigation serves to study the following important problem in cosmogony, to which micrometric measures contribute nothing, and which can otherwise only be examined from the standpoint of theory.

If we admit a common origin to the stars of the Milky Way, a general coincidence in their axes of rotation seems not improbable, especially as such an approximate coincidence occurs in the members of the solar system. If the coincidence was exact, the direction must be that of the poles of the Sun, or, approximately, that of the pole of the ecliptic. On the other hand, since the stars of the Milky Way are supposed to be arranged in the general form of a flattened disc, we should more naturally expect that the axes of rotation would be symmetrically situated with regard to it, or would coincide with its shortest dimension. According to this theory, then, the axes of rotation would be directed towards the poles of the Milky Way. If now we suppose that a great number of variable stars were distributed over the heavens, it is evident that those seen in the direction of their axes would not appear to vary, since, as they turned, they would always present the same portions of their surfaces to the observer. Those at right angles to this direction would show the greatest variation, and, other things being equal, would appear to be more numerous, since they would be more likely to be detected. If then the axes are coincident, we should expect that most of these variable stars would lie along the arc of a great circle whose pole would coincide with their axes of rotation."

"Thirty-one stars are known whose period is less than 72 days. Of those, six belong to the fourth class, or that of *β Persei*, in which the variation is probably due to the interposition of an opaque eclipsing satellite. Of the remainder, seven may be excluded, since they are red, and may belong to the second class, or that of *o Ceti*. Eighteen remain, whose periods vary from less than a day to 54 days, and which may be placed in the third class. All lie within 16° of a circle whose pole is in R. A. 13h, Dec. + 20°. The distances of eleven are from 0° to 5°, of five at distances of 8° and 9°, one at 14° and one at 16°. The average distance is 5.°5, while, if the stars were distributed at random it should be 30°."

THE dome erected by Sir Henry Bessemer for the reception of his new and powerful telescope is now nearly finished. The telescope itself has arrived from the makers, and is now ready to be set up. It has been constructed on a plan devised by Sir Henry Bessemer, which it is believed will permit of telescopes being made on a much larger and more powerful scale than even the present one, which is the largest in the world. The present instrument is capable of being directed to any part of the heavens at the option of the observer. The upper portion of the dome is made of glass, with windows facing in every direction, and within there will be placed mirrors of silvered glass, which is part of the new invention, silvered glass being used in place of metal. The room and dome with its windows will revolve and keep pace automatically with every motion of the telescope, and the upper end of the instrument will reach a height of about forty-five feet.

WASHINGTON, *March* 24. W. C. W.

DISCREPANCY IN RECENT SCIENCE.

There are two classes of statements in current scientific literature that do not harmonize. Their teachings are opposite ; yet, the sayings are daily used by men who believe both to be true. One series of doctrines is known as the "Conservation of Energy;" the other, the "Nebular Hypothesis." The structure of nature rests on one, while the history of cosmic evolution is based on the other. Then they should agree. Men are fascinated with cosmogony, and for ages have sought the laws by which the Universe developed. This research culminated in the existing Nebular Hypothesis. Other fields of study were opened, man scrutinized his environment, analyzed matter, searched for its ruling laws and summed up results in the doctrine of the Conservation of Force. Now the laws by which nature was in the past evolved, and is in the present governed, must be, and are the same. Such does not seem to be the teaching of some late popular books on science.

By a generalization of late research it is annnounced that the Universe is a unit. All suns visible in the telescope are composed of similar material, since they emit light, having like properties, and are dominated by the same laws of gravity and motion as rule the solar system.

Like matter, like laws, is the postulate of nature for all time. Some scientists ignore this apparent truth, as will be seen in comparing ideas advanced in recent works.

The fundamental axiom in the law of the interaction of force is, that when one mode of energy appears, another vanishes, and vice versa.

No form of force can become sensible without the retirement of another of equal intensity. This mutual displacement never ceases for an instant, and the system of nature is kept up by the flow, interchange and conversion of force. Conservation is the law of energy, and no one force can long act without waning and giving rise to another. Gravity, motion, electricity, magnetism, chemism, heat and light, are forms in which energy exists; yet one never can work eternally by itself, but must suffer conversion into another mode of power. Motion in molecules evolves heat, and heat acting upon still molecules appears as motion. Chemism acts, gives rise to heat and in doing so expires ; or it may exhaust its energy in conserving electricity, which in turn may develop into heat. Numberless like instances might be given to prove the conservation of energy, were they necessary, but they are not; this great law is universally accepted by students of nature throughout the world, and the closest reasoner cannot find objection to this deduction of science. Among many facts revealed by the discovery of the laws of force, one only is

here sought to be made prominent, that relating to the evolution of heat. Heat cannot come of itself; some other mode of energy must precede it. Suppose all matter in existence to be dissociated, resolved to gas so attenuated that no two atoms touch. It would have "potency" for future development of every form of force, but at that time only one would be in existence—gravity. It could reign supreme only for an instant; obeying the law, it would suffer "conservation," and give rise to motion.

Hence, motion is the second mode of energy, and all the heat that ever existed came later. The only sources of heat known are motion and chemical action, itself a most rapid motion. Gravity caused the movement of original atoms, bringing them near enough to be within the influence of affinity, which acting, conserved heat, the fourth form of force awakened in the evolution of atoms hitherto separated. Or a little heat might have been derived from collision of atoms not having affinity; in either case heat had antecedent forces. Heat is not a primal affection of matter, but secondary; being always preceded by gravity and motion. And molecules must be separated by space in order that gravity can cause motion to appear and vanish in heat. It is not conceivable that primordial dissociated matter should have obeyed any impulse at first, save gravity, then motion, then Chemism, then heat and subsequently all other states of force.

The Nebular Hypothesis seeks to account for the evolution of all solar systems from primordial dissociated matter, requiring as Helmholtz says: "Several cubic miles to weigh a single grain." Nearly all physicists accept this theory, and admit that all existing matter was once in this condition of gas. It seems, by reason of known laws of matter, to be true. Thus, no two atoms coalesced; they were as far apart in proportion to their diameters, as the Sun and Polaris. No ascertained law of nature disputes this theory; and within limits of human knowledge, it must be so. Matter dissociated is in its most primitive condition; and nature begins in simplicity and develops complexity. Matter in fluid states is complex, and shows itself to have been wrought by force. All analogy points to the fact that at one time in the history of matter, its atoms were entirely separated; in which condition no force whatever save gravity was in existence to act thereon.

Yet, strange to say, some advocates of the nebular theory teach that this rare gas was intensely hot! They call it "fire mist,[1]" and aver that it was hotter than the sun is now! We read[2]; "There was a time when the materials composing it (the Universe), were masses of glowing vapor," and "we find that the further we go back into time the hotter the sun must have been. Since we know that heat expands all bodies, it follows that the sun must have been larger in past ages than it is now, and we can trace back this increase in size without limit. Thus we are led to the conclusion that there must have been a time when the sun filled up the space now occupied by the planets, and must have been a very rare mass of glowing vapor." True, the materials of the sun extended into a ball of gas thousands of millions of miles in diameter, far lighter than hydrogen; but the gas was intensely cold. No law of matter or force known to man; nor any analogy in nature leads to the conclusion that the primitive cosmical sphere of atoms was hot. It was cold and dark, neither chemism, heat, or light appeared until gravity made conservation in motion, making chemical action possible. Affinity must have been slow at first, so that heat could not have appeared until after ages of chemical and molecular activity had expired, and heated fluid nuclei begun to condense and shine. The original cosmical mass was as dark, cold and silent as interstellar space is now, and "fire mist" never had a place in nature. If the primeval "glowing vapor" ever existed, then the greatest monument ever reared by man, the "Law of Interaction of Force" falls crumbling to final ruin.

NOTES.

SOLUTION OF STARCH.—Zulkowsky proposes to make starch perfectly soluble in water by heating it to 190° C. along with glycerine. This process is most successful with potato-starch, less so with wheat-starch, and very difficult with rice-starch.

SALICYLIC ACID IN TEXTILE MANUFACTURES.—Dr. F. von Heydon recommends salicylic acid to be applied in dilute solution to woollen yarns, and to be mixed with sizes to prevent mildew, unpleasant smells, &c. Five grms. acid are sufficient for a litre of size.

ACTION OF HYDROCHLORIC ACID UPON METALLIC CHLORIDES.—The chlorides which are rendered more soluble by hydrochloric acid are divided into two groups; the one (*e.g.*, mercuric chloride) exceedingly soluble in the concentrated acid form with it crystalline compounds; the other (*e.g.*, silver chloride) very sparingly soluble, even when heated, yield on cooling the chloride considered as anhydrous.—A. DITTE.

ACTION OF CAUSTIC LIME UPON PURE SOLUTIONS OF SUGAR AND RAW BEET-JUICE.—If free alkalies or alkaline earths are added to a solution of sugar the rotation which sugar occasions in polarized light decreases, and is restored on neutralizing the alkaline liquid with acetic acid.—F. DESOR.

NEW STUDIES ON THE PART PLAYED BY BONE-BLACK IN THE SUGAR MANUFACTURE.—Free lime is almost entirely absorbed by bone-black. Salts of lime and potash are also absorbed to a certain extent. Potash and lime, the latter in saline form, promote each other's absorption.—H. PELLET.

CHEMICAL CHANGE OF STARCH ON EXPOSURE TO STEAM AT A HIGH PRESSURE.—A heat of 140° to 150°, and consequent pressure of 3½ to 4½ atmospheres convert 71 per cent. of starch into glucose. Dr. M. Stumpf considers that with the aid of 1 to 2 parts of acid per thousand saccharification may be carried so far as to render the use of malt unnecessary.

DECOMPOSITION OF SALTS BY LIQUIDS.—The laws of dissociation by heat, applicable to the decomposition of salts by pure water and saline acid solutions, apply also to decomposition by alcohols.—A. DITTE.

INFLUENCE OF THE SOIL UPON THE TANNIN OF OAK BARK.—A comparison was made between the bark of young oaks grown respectively upon sandy loams, upon peaty soil which had been once burnt, and upon a similar soil thrice burnt. The proportion of tannin was found higher in case of the peaty soils.—M. FLEISCHER.

INFLUENCE OF MANURES ON THE APPEARANCE OF DISEASE AND THE PROPORTION OF STARCH IN POTATOES.—Three plots dressed with stable manure showed 6, 6, and 5 per cent. of diseased tubers. Plots where superphosphate and small quantities of ammoniacal superphosphate were used did not increase the percentage, but with larger proportions of the latter it rose to 8 per cent. Chili saltpetre was attended by a proportion of 11 per cent., and when used as a top-dressing 12 per cent.—M. MARCKER.

INFLUENCE OF BORAX ON THE DECOMPOSITION OF ALBUMEN IN THE ANIMAL ORGANISM.—The ingestion of borax is found to increase the decomposition of albumen.—M. GRUBER.

TITRATION OF BISMUTH SUBNITRATE.—This process is based upon the facts that as to 9·9074 grm. of monohydrated sulphuric acid correspond to 1 grm. anhydrous nitric acid these two weights of acids will require the same quantity of alkali for exact saturation, and that bismuth subnitrate is capable of yielding all its nitric acid to an excess of alkali on boiling.—E. BAUDRIMONT.

BOOKS RECEIVED.

THE POWER OF MOVEMENT IN PLANTS. By CHARLES DARWIN, LLD., F. R. S., assisted by FRANCIS DARWIN. D. Appleton & Co., Bond street, New York. 1881.

The announcement of a new work from Dr. Darwin brings joy to the heart of every naturalist, and the present volume will be much cherished by botanists, because it introduces a line of research which is comparatively unworked and one which promises interesting results to those who have time and patience to continue it.

The object of Dr. Darwin in writing this book was to describe and connect together several large classes of movements common to almost all plants, which is chiefly noticed in climbing plants, the tips of which revolve, bending successively to all points of the compass. This movement is called by Darwin *circumnutation*, and a plant is said to *circumnutate*.

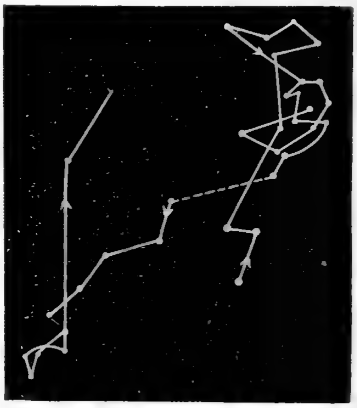
In the course of the present volume it is shown that all growing parts of every plant are continually circumnutating, though often on a small scale. Even the stems of seedlings before they have broken through the ground, as well as their buried radicles, circumnutate, as far as the surrounding earth will permit. In this universally present movement we have the groundwork or basis for all the varied movements which are essential to the requirements of plant life.

Thus the great sweeps made by the stems of twining plants, and by the tendrils of other climbers, result from a mere increase in the amplitude of the ordinary movement of circumnutation. The position which young leaves and other organs ultimately assume is acquired by the circumnutation movement being increased in one direction. The leaves of various plants are said to sleep at night, and it is shown that their blades then assume a vertical position through modified circumnutation in order to protect their upper surfaces from being chilled through radiation. The movements of various organs to or from the light are all modified forms of circumnutation, as are the equally prevalent movements of stems, &c., toward the zenith, and of roots toward the centre of the earth. The method of observation employed by Darwin is thus explained:

" Plants growing in pots were protected wholly from the light, or had light admitted from above, or on one side as the case might require, and were covered above by a large horizontal sheet of glass, and with another vertical sheet on one side. A glass filament, not thicker than a horsehair, and from a quarter to three-quarters of an inch in length, was affixed to the part to be observed by means of shellac dissolved in alcohol. The solution was allowed to evaporate until it became sufficiently thick to set in two or three seconds, and it never injured the tissues, or even the tips of tender radicles. To the end of the glass filament an exceedingly minute bead of black sealing wax was cemented, below or behind which a bit of card with a black dot was fixed to a stick driven into the ground. The weight of the filament was so slight that even small leaves were not perceptibly pressed down. The bead and dot on the card were viewed through the horizontal or vertical glass plate (according to the position of the object), and when one exactly covered the other, a dot was made on the glass plate with a sharply-pointed stick dipped in thick Indian ink. Other dots were made at short intervals of time, and these were afterward joined by straight lines. The figures thus traced were therefore angular, but if dots had been made every one or two minutes, the lines would have been more curvilinear, as occurred when radicles were allowed to trace their own courses on smoked glass plates. To make the dots accurately was the sole difficulty, and required some practice. Nor could this be done perfectly when the movement was much magnified, say 30 times and upward, yet even in this case the general course may be trusted."

To make this clear we give a diagram of one of the most simple of Darwin's experiments, and the following further explanation:

"*Brassica oleracea*" (cruciferæ.)—Radicle. A seed with the radicle projecting .05 inch was fastened with shellac to a little plate of zinc, so that the radicle stood up vertically; and a fine glass filament was then fixed near its base, that is, close to the seed coats. The seed was surrounded with little bits of wet sponge, and the movement of the bead at the end of the filament was traced (see figure) during sixty hours. In this time the radicle increased in length from .05 to .11 inch.



Brassica oleracea, circumnutation of radicle traced on horizontal glass from 9 A. M., January 31, to 9 P. M., February 2. Movement of bead at end of filament magnified about forty times.

We trust that those who would take up this subject will consult this work, as the amount of detail there given is most essential to a thorough comprehension of this study, but in case any of our readers are unable to do so, the explanation we have given may suffice.

The chapters on the sleep of plants are most interesting and instructive, and many discoveries relating to this phenomenon are presented.

There are also certain movements in plants which are not due to circumnutation, such as when a leaf of the Mimosa is touched it suddenly assumes the position as when asleep, but this movement occurs from a different cause to that which produces the sleep of plants. The sleep movement of plants is due to modified circumnutation; this would not happen from a touch.

Space will not permit us to further describe this important branch of the subject, but we hope on a future occasion to again refer to it, and offer some illustrations of the most striking instances. But as Mr. Darwin observes, it is impossible not to be struck with the resemblance between the sleep movements of plants and many of the actions performed unconsciously by the lower animals. With plants an extraordinarily small stimulus suffices; and even with allied plants one may be highly sensitive to the slightest continued pressure, and another highly sensitive to a slight momentary touch. But the most striking resemblance is the localization of their sensitiveness and the transmission of an influence from the excited part to another which consequently moves. Yet plants do not of course possess nerves or a central nervous system; and we may infer that with animals such structures serve only for the more perfect transmission of impressions, and for the more complete intercommunication of the several parts.

INFLUENCE OF THE VENTILATION OF MUST UPON ALCOHOLIC FERMENTATION.—E. Rotondi considers that ventilation mechanically promotes the decomposition of the sugar, and acts also chemically, because the albumenoid bodies are transformed into more diffusible matters, and because oxygen by increasing the quantity of ferment indirectly intensifies the fermentation.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, APRIL 2, 1881.

It has been well said, that the poorest day that passes over us is the conflux of two eternities: it is made up of currents that issue from the remotest past, and flow onward into the remotest future.

On the 27th of June, 1829, an event took place which was to have a marked influence on the intellectual development of the United States, for on that day James Smithson died at Genoa, Italy, bequeathing his whole fortune to the citizens of the United States, in trust, "*for the increase and diffusion of knowledge among men.*"

On the 6th of December, 1838, President Van Buren had the satisfaction of announcing to Congress that the claim of the United States to this legacy had been fully established, and that the money had been received by the Government.

The question then arose, what plan could be devised to carry out the intentions of the testator. In other words, how could "the increase and diffusion of knowledge among men" be best accomplished.

One of the first proposals for utilizing the Smithsonian fund was a scheme of founding a university of high grade, to "teach Latin, Greek, Hebrew, Oriental languages, and other branches of learning, including rhetoric, poetry, laws of nations, &c." Fortunately, such counsel did not prevail, and after nearly eight years of debate, and even a proposal to return the money to England being voted on, a bill was passed by Congress organizing the Smithsonian Institution on its present basis.

Such, briefly stated, was the origin of the Smithsonian Institution, and in memory of its founder the present Secretary, Professor Spencer F. Baird, directed Mr. William J. Rhees to compile a biography* of James Smithson, this work being one of the most recent publications of the Institution.

The general scope of this work is good, and it must be admitted that some account of the establishment of this Institution was called for. We must, however, express our regret that such an elaborate description of Smithson's aristocratic connections was presented, especially as the history would have been equally complete without this superfluous addition. The connection of the "proud" Dukes of Northumberland and Somerset with Smithson was hardly of a nature to be recorded in a form which should constantly bring the facts before the present generation and posterity.

The circumstances of Smithson's birth cannot be ignored, but there is no reason why they should be paraded before the public; we therefore would have dispensed with the portrait of the first Duke of Northumberland in this volume, and relegated the history of his life and death to the highest shelf in the Smithsonian Library.

Stript of such surroundings, the memory of Smithson must ever be dear to the people of this country. He was a man thoroughly imbued with the spirit of true science, and an active and industrious laborer in one of the most interesting and important branches of research—"mineral chemistry." His happiest hours were spent in the laboratory, where he carried on a series of experiments, which were recorded in the transactions of the Royal Society of London and other scientific journals of the day. Such being the direction of Smithson's scientific pursuits, we trust that the advancement of the physical sciences may claim the attention of the officers of this institution, and that they may be more duly represented in future reports.

Since the death of Smithson, Chemistry has attained a higher rank among the exact sciences. New methods and instruments of analysis have been introduced, while other branches of science have advanced at an equal ratio. New means "for the increase and diffusion of knowledge among men," have come to light, and among these the production of improved scientific manuals, and the increased number and excellence of scientific periodicals and journals, may be mentioned as having largely contributed to such results. Science at the present day is no longer monopolized by a select few, but is claimed as the common heritage of the thousands who have the intelligence to appreciate its value in developing the highest faculties of man.

Thomas Carlyle considered that "to know the divine laws and harmonies of this Universe must always be the highest glory of a man, and not to know them the highest disgrace for a man." This Journal represents one of the latest attempts to place at the disposal of all interested in scientific pursuits and human progress, a weekly journal worthy of the subject discussed. We are glad to find that our efforts have been appreciated, and the constant receipt of letters of welcome, co-operation and aid, increases our hopes for the future. Among our latest subscribers, we find three residing in Japan, one in Lucknow, India, another in New Zealand, and the directors of the Royal observatories of Brussels, Lisbon, and Rome have added their names. If "Science" is thus in demand in foreign countries, we trust to find our home subscription list rapidly increase, which will enable us to enlarge and improve the journal in various ways, thus adding to its usefulness.

Lord Brougham observed, that to instruct the people in the rudiments of philosophy, and to obtain

* James Smithson and his bequest, by William J. Rhees, published by the Smithsonian Institution, Washington, 1880.

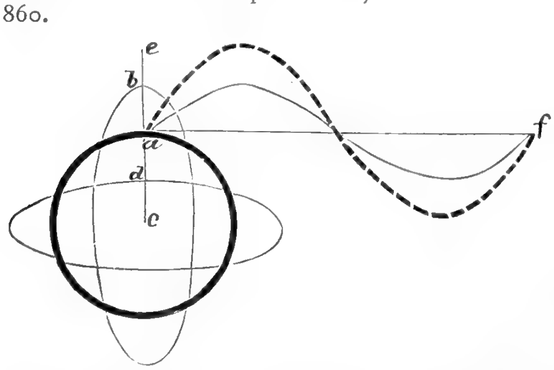
for the great body of our fellow creatures that high improvement, which both their understanding and their morals fit them to receive, is an object sufficiently brilliant to allure the noblest ambition. Without claiming such lofty aspirations, the promoters of "SCIENCE" yet look forward to the time when their efforts to establish this journal may be recognized as at least a step in that direction.

ON THE AMPLITUDE OF VIBRATION OF ATOMS.

PROF. A. E. DOLBEAR, TUFTS COLLEGE, MASS.

There is now sufficient evidence for the belief that the kinetic energy of atoms and molecules consists of two parts, one of which is the energy of translation or free path, the other of a change of form due to vibrations of the parts of the atom or molecule toward or away from its centre of mass. The pressure of a gas is immediately due to the former while the temperature of the gas depends solely upon the latter. These two forms of energy must indeed be equal to each other in a gas under uniform conditions; for if one exceeded the other in energy when there is as free a chance for exchange as among the atoms of a gas, there would result an increase of pressure on the one hand, or an increase of temperature on the other. Now the kinetic energy of a mass m and velocity v is expressed by $\frac{m v^2}{2}$ and applies as well to an atom as to a musket bullet, and if we take the mass of the hydrogen atom as unity and employ the calculated velocity of hydrogen atoms at 0° Cent. and 760 mm. pressure, namely 1860 metres per second, the energy will be $\frac{(1860)^2}{2}$.

We know also how many times the hydrogen atom vibrates per second, by dividing the velocity of light per second by some chosen wave length λ; so that $n = \frac{v}{\lambda}$. If attention be now directed to the vibrating atom possessing the same energy as in the free path movement, it will be seen that its *velocity of vibration* must also be equal to 1860 metres per second. But vibratory velocity is the product of a number n into an amplitude a, so that $v = na = 1860$.



Adopting the vortex-ring theory of matter, the dark ring represents the atom which, when executing its simplest vibration assumes consecutively the conjugate ellipses and any point a in the circumference will move over the line $b\ d$, the latter distance constituting the amplitude of the vibration. The limits to this movement must clearly be between $b\ d = 0$ when there is no vibration, the absolute zero of the atom and $c\ e$ which can never exceed $\frac{1}{2}\ \pi r$ and indeed must always be less than that value; for when half the major axis of the ellipse is equal to that it has become a straight line. As atomic vibrations result in undulations in ether it is evident that amplitude $b\ d$ will give an undulation $a\ f$ shown in continuous line, while maximum amplitude $c\ e$ would give same wave length shown in broken line. The greater the actual thickness of the ring the less must be the possible maximum amplitude.

The amplitude then becomes comparable with the diameter of the atom, and in this discussion the assumed diameter is the one given by Maxwell, namely .0000005 mm.

The numerical value of $\frac{1}{2}\ \pi r$ for such a diameter is .0000004 mm. which represents the theoretical maximum amplitude for a hydrogen atom.

If any hydrogen wave length be taken, say $C =$ .0006562 mm. the ratio of wave length to maximum amplitude is $\frac{.0006562}{.0000004} = 1640$, that is wave length is 1640 times such amplitude. But hydrogen C is not the fundamental vibration, but according to Stoney is the 20th harmonic of a fundamental having a wave length of .013127714 mm. and $\frac{.013127714}{.0000004} = 32819$. That is, it is 32819 times greater than the amplitude.

Now, Sir William Thomson, in his calculations on the amount of energy in the ether, assumed that the amplitude should not exceed one-hundredth of the wave length, but that value is evidently very many times too large. An undulation with the wave length of this fundamental for hydrogen is nearly twenty times longer than the longest one that can be seen; and as the sensation of light depends upon wave length and not upon amplitude, or what the energy of the ray, it follows that Dr. Drapers' deductions concerning the temperature of bodies beginning to be luminous will not necessarily apply to gases, for when extra energy is imparted to the atoms of a gas it is the amplitude of their vibrations that is affected, and if the impacts are sufficiently frequent some of the harmonic vibrations may appear continously, but they will not thereby necessarily indicate a higher temperature, but show that the energy is distributed in two or more periods, some of which have resulting undulations which may be seen; but this will depend upon the density of the gas. Suppose a body capable of vibrating a times per second for its fundamental, be struck b times per second; then will the rate of vibration be interfered with $\frac{a}{b}$ times. If b be less than a, then will the fundamental vibration have more than its required interval between impacts, and a certain number of these fundamental vibrations will be made per second. If b be equal to a, then, after the first impact, a will vibrate in its own period with increasing amplitude, without interference. If b be greater than a then will the impacts interfere in all phases of the vibrations, the fundamental will be destroyed, and only some harmonics and irregular vibrations will be possible; but the number of impacts

per second depends upon the density, and in solids and liquids this secures the destruction of the fundamental vibrations as the energy of vibration is increased, at the same time developing the multitude of irregular ones shown in the spectrum; while in a gas the number of impacts per second is many times less than the regular rate of vibration, and this secures the time for either fundamental or harmonics, and the consequent spectra. The number of vibrations n the hydrogen atom makes when the wave length is .0131277 mm. will be $n = \frac{v}{\lambda} = \frac{3 \times 10^{11}}{.131277} = 2286 \times 10^{10}$.

Let v^1 represent the velocity in free path motion of the atom at 0° Cent. and 760 mm. pressure = 1860-000 mm. Their amplitude a will equal $\frac{v^1}{n} = \frac{1860000}{2286 \times 10^{10}}$ $= 8134 \times 10^{-11}$ m. Comparing this with the diameter of the atom $\frac{8134 \times 10^{-8}}{5 \times 10^{-7}} = .162$. That is the amplitude is equal to .162, the diameter of the atom at 0°.

Assuming a temperature higher than this, say 273° Cent., then the energy of the atom in its free path motion compared with that it has at 0° will be as $\sqrt{2}$: 1 and 1 : $\sqrt{2}$: : 1860 : 2630 m. per second, and as be fore amplitude a will equal $\frac{v^1}{n} = \frac{2630000}{2286 \times 10^{10}} =$ 115×10^{-7}. This compared with the diameter of the atom gives $\frac{115 \times 10^{-7}}{5 \times 10^{-7}} = .23$. That is, the amplitude is equal to .23 the diameter at 273° Cent., a difference of .068 for 273°.

With same data the maximum temperature of the hydrogen atom may be calculated for as

$$(.162)^2 : (.7854)^2 : : 273^\circ : 6419^\circ$$

which would be the highest temperature the atom could have if it could have such an amplitude, and this will be reduced as the thickness of the ring increases. Any additional energy the atom would receive could not possibly heat it but would be expended either in rotating it or in giving to it a free path motion. In like manner the amplitude for a single degree is found to be .0098 diameter, or very nearly one-hundredth the diameter.

For other atoms than hydrogen when they have the same energy their amplitude must vary inversely as their mass, so that for oxygen the amplitude at 273 would be $\frac{.162}{16} = .01$ its diameter, and its maximum temperature will be $6419 \times 16 = 102704^\circ$ Cent., a number altogether too high for the same reason as was given for hydrogen, namely it assumes that the ring has no thickness.

If these computations have any value they may be applied to the solution of the temperature of the sun.

The elements having the greatest density must have the highest maximum temperature. In the sun twenty-five elements have been determined spectroscopically and the average density of these twenty-five is 63. Now on the hypothesis that these elements exist in equal quantities in the sun, which is not very probable, the maximum temperature of that body woulp be about 400000° Cent.

As at absolute zero each atom is quite independent of every other atom, that is, matter has not a molecular structure, so, at certain high temperatures that differ for different substances, all molecular groupings must be broken up and the atoms are quite dissociated from each other, and this dissociation must occur before the maximum temperature is reached; it would appear that whenever at the sun the temperature approached its maximum, then the elements would be elementary, uncombined, and if compounds are observed or appear probable from phenomena witnessed, that will be the best evidence that the temperature is decidedly lower than the above figure. For hydrogen the dissociation temperature is only about 700° Cent. which is only about one-ninth its maximum.

MARSH'S ODONTORNITHES.*

Were there no other proofs of his zeal and success in extending the bounds of knowledge, the writer of this magnificent monograph would be famous as—for ten years at least,—the sole discoverer, describer and possessor of the remains of Extinct Toothed Birds of North America.

It may befall almost any diligent explorer to find the remains of some species previously unknown, but few have had— or so well-deserved—the privilege of presenting to the world a new series of facts embodying a new idea, at once easily appreciated by the many, and serving the few as material for profound consideration. That a bird with teeth is, most literally, a *rara avis*, may be conceded without extensive acquaintance with either Latin or Ornithology; on the other hand, it is probable that naturalists have not yet wholly realized the import of this fulfillment of a prediction which might have been made legitimately—though we are not certain that it ever was —at any time during the last twenty years.

Aside from the Appendix, the present volume embraces detailed descriptions of the bones and teeth of *Hesperornis* and *Ichthyornis*; a general description of the "Restoration" of each genus; and a "Conclusion" embracing the author's views upon the taxonomic relations, and probable evolution of these two forms, together with *Archæopteryx*.

The following are the principal characteristics of the two American genera, chiefly as recapitulated upon p. 187. In *Hesperornis*, the articular ends of the vertebral centra are saddle-shaped, as in recent birds; in *Ichthyornis* they are biconcave, as in many fishes: *Ichthyornis* has a prominent sternal keel for the attachment of the muscles of the well-developed wings; in *Hesperornis*, the sternum is without a keel, and each wing is represented by only a rudimentary humerus: the wing-bones of *Ichthyornis* have tubercles evidently for the attachment of feathers; no signs of feathers have been observed with *Hesperornis*, but they doubtless were present in life: in both genera, the caudal vertebræ are few, so that the bony tail is short as in recent birds: in both, the mandibular rami seem to have remained permanently ununited by bone: in both, as indicated by casts of the cranial cavity, the prosencephalon was narrower than in recent birds of

* Odontornithes: A Monograph on the Extinct Toothed Birds of North America; with thirty-four plates, and forty woodcuts. With an Appendix giving a Synopsis of American Cretaceous Birds. By Othniel Charles Marsh, Professor of Palæontology in Yale College, Memoirs of the Peabody Museum of Yale College, vol. 1; pp. 201. This memoir will also form vol. vii, Survey of the 40th parallel.

similar size, a point of much interest, in view of what has been noted by Prof. Marsh with regard to the brains of extinct Mammals: finally, both forms had *well-developed teeth in both jaws*, but those of *Hesperornis* were implanted in a continuous groove, while those of *Ichthyornis* had separate sockets.

Prof. Marsh calls attention to the peculiar combination, in *Ichthyornis*, of a low feature—the biconcavity of the vertebræ—with a comparatively high method of implantation of the teeth, and adds: "Better examples than these could hardly be found to illustrate one fact brought out by modern science, that an animal may attain great development in one set of characters, and at the same time retain other low features of the ancestral type. This is a fundamental principle of Evolution."

Naturally, the teeth are described and figured with especial fullness and accuracy. Their general features are distinctly reptilian, as would have been inferred. Curiously enough, in neither genus does the dental series reach the tip of either jaw, and, in *Hesperornis*, "the extremity of the premaxillary bone, back to the nasal openings, has its surface pitted with irregular vascular foramina, indicating. apparently, that it was once covered with a horny bill, as in modern birds." P. 8.

With the exception of *Archæopteryx*, all the known odontornithic remains are in the Museum of Yale College, but their discoverer is clearly of opinion that more are to be found:

"These three ancient birds, so widely different from each other, and from all modern birds, prove beyond question the marvellous diversity of the avian type in mesozoic time, and also give promise of a rich reward to the explorer who successfully works out the life-history of allied forms, recorded in ages more remote." P. 189.

He even ventures to define the leading features of the, at present, hypothetical progenitor of the entire group of birds: "In the generalized form to which we must look back for the ancestral type of the class of birds, we should therefore expect to find the following characters: Teeth in grooves; vertebræ biconcave; metacarpal and carpal bones free; sternum without a keel; sacrum composed of two vertebræ; bones of the pelvis separate; tail longer than the body; metatarsal and tarsal bones free; four or more toes, directed forward; feathers rudimentary or imperfect; quadrate bone free." P. 188.

As compared with this generalized form, our modern birds, while endowed with intense functional activity, and in some structural features—especially as to their true dermal appendages—a most highly specialized group, are nevertheless, odontologically considered, degenerated and retrograded creatures.

The general bearing of the facts given in this memoir upon the question of evolution has been well stated by Prof. Marsh upon a previous occasion.

"*Compsognathus* and *Archæopteryx* of the Old World, and *Ichthyornis* and *Hesperornis* of the New, are the stepping-stones by which the evolutionist of to-day leads the doubting brother across the shallow remnant of the gulf, once thought to be impassable."

So far we have had to deal either with facts, or with hypotheses based upon those facts and warranted by the prevailing opinions respecting evolution in general. There remains to be considered the bearing of these same facts upon the zoological relations of the toothed birds to the rest of the class. Here there is room for very wide disagreement, and the only point, perhaps, upon which all seem to be in accord, is that the Birds, as a whole, form a *class* of vertebrates, whether or not they should be combined with the reptiles as a super-class or sub-branch—Sauropsida.

The advantages of employing a single technical term like *odontornithes* in place of *aves dentatæ* or *toothed birds* will be generally conceded, and the use of the term as a convenient designation of certain forms need not imply more than is implied by the words *swimmer*, *flier*, *apoda*, etc. The real question is, dó the toothed birds constitute a natural subdivision of the class Aves, comparable for instance with the Marsupials among the mammalia? If not do they constitute an order or a family, or, finally, are they—or some of them—simply representatives of two or more natural groups, differing from the other members of those groups, and associated together, by the possession of teeth?

In a natural classification, we expect to find animals collocated either because they agree in many particulars, or because they have in common one or, more features of primary importance For example notwithstanding their immense variety in size, form, habit, existing birds present a remarkable uniformity of structure, even in some apparently insignificant details. On the other hand, although *Amphioxus* differs from all other Vertebrates in so many respects that nearly all generalizations as to the branch must be accompanied by a qualification, yet it shares with the rest a developmental feature and a general arrangement of organs which keep it within the branch and separate it from all other animals, excepting perhaps the Ascidians.

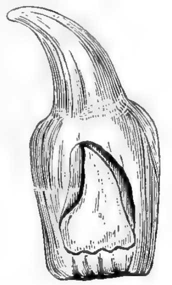
Prof. Marsh regards *Archæopteryx*, *Hesperornis*, and *Ichthyornis*, as the representatives of as many orders of the subclass Odontornithes, to which he applies the names Saururæ, Odontolcæ, and Odontotormæ. The first of these names had been employed already by Hæckel and Huxley, who, however, had made the Saururæ, Ratitæ(ostrich, etc.) and Carinatæ, (all other birds) subclasses of the class Aves. Marsh does not say what he thinks should be done with the Ratitæ, but if he is correct in his opinion (p. 3.) that "*Hesperornis* and *Ichthyornis* differed more from each other than do any two recent birds," it would seem to follow that the Ratitæ can no longer constitute a subclass of the recent and toothless birds.

In the condensed statement of the characters of the orders (p. 187) it is shown that we are unacquainted with the mode of implantation of the teeth of *Archæopteryx*, with the form of its vertebræ and sternum, and with the extent of union of the mandibular rami. The characters enumerated are the *presence of teeth*, *small wings*, *separate metacarpalia and a bony tail longer than the body*.

It will be seen that, excepting the teeth, any generalization respecting the Odontornithes as a whole, must be accompanied by a qualification respecting one or two of the orders. Prof. Marsh points out that the three groups present unequal degrees of affinity. But even if we exclude *Archæopteryx*, the only characters which are at the same time common to the

Odontolcæ, and Odontotormæ and absent from recent birds, are the *narrowness of the prosencephalon*, *the persistent separation of the mandibular rami and the presence of teeth.*

That the presence of teeth has been regarded by Prof. Marsh as the principal—if not the only essential—characteristic of the Odontornithes, is indicated by the following passages from the present work, or from previous papers.



TOOTH OF *Hesperornis Regalis*, SHOWING GERM OF YOUNG TOOTH.

"Both of these types possessed teeth, a character hitherto unknown in the class of birds, and hence they have been placed by the writer in a separate sub-class, the Odontornithes." P. 3.

"That *Archæopteryx* belongs to the Odontornithes, the writer fully satisfied himself by a personal examination of the well-known specimen in the British Museum. The teeth seen on the same slab with this specimen agree so closely with the teeth of *Hesperornis*, that the writer identified them at once as those of birds and not fishes." P. 186.

In speaking (p. 191) of the "bird remains found in the Green-Sand deposits of New Jersey," our authoı says; "as neither jaws nor teeth have yet been detected, it is at present impossible to say whether the Eastern species belong to the Odontornithes."

Before the discovery of the teeth, he had characterized the *Hesperornis regalis* as a "gigantic diver related to the Colymbidæ." His preliminary description of the same bird had been to the same effect, with the addition "that it differs from the Colymbidæ so widely in the structure of the pelvis and posterior limbs as to demand a place in at least a separate family."

In the present publication, however, our author is of opinion that "the struthious characters seen in *Hesperornis* should probably be regarded as evidence of real affinity, and in this case *Hesperornis* would be essentially a gigantic swimming ostrich." P. 114.

That Prof. Marsh's opinion as to the taxonomic value of the teeth is shared by zoologists generally, is shown—at least negatively—by the absence of dissent from his own views and from those of such reviewers as Newton and Woodward. The former speaks of the "teeth, whence the *Ichthyornis* has been made the type of a distinct sub-class." The latter, writing of the same genus, says: "The possession of teeth and biconcave vertebræ, although the rest of the skeleton is entirely avian in type, obviously implies that these remains cannot be placed in the present group of birds, and hence a new sub-class, Odontornithes is proposed for them." In the added note, respecting *Hesperornis*, Woodward does not state whether he was then aware that the vertebræ of that genus lacked the biconcave character. Hence it is not certain whether he would regard it as an odontornith by reason of the teeth alone.

Prof. Huxley does not distinctly mention the degree of separation of the toothed birds from the rest, but he says that the *Hesperornis regalis* "in a great many respects is astonishingly like an existing diver or grebe, so like it indeed, that had this skeleton been found in a museum, I suppose—if the head had not been known—it would have been placed in the same general group as the divers and grebes of the present day."

So far as I am aware, no objection to the erection of a sub-class upon a purely dental basis, has been offered, even upon the part of some who have not usually been slow in critcising our author's conclusions.

Yet Prof. Marsh himself appears to be by no means settled in his conviction as to the taxonomic relations of the forms in question, since his "Conclusion" contains the following qualified expression of opinion: "For the present, at least, it seems advisable to regard the Odontornithes as a sub-class, and to separate them into three orders."

The above intimation of a willıngness to review this part of the subject removes the hesitation which one naturally feels in differing from the highest—and, in one sense, the only—odontornithological authority, and I therefore venture to offer certain considerations which seem to have been overlooked hitherto.

1. Are the other characters of the toothed birds such as to warrant their separation as a sub-class? In other words, can we conceive of *edentulous* Odontornithes as we have Vertebrates without vertebræ, and Edentates provided with teeth?

2. Why should the presence of teeth in certain birds be accounted of more taxonomic significance than the absence of the same organs in the members of other classes? The truly edentulous edentates are held to form merely families or sub-orders; the (toothless) turtles are commonly regarded as an order of reptiles; and Prof. Marsh himself has established the sub-order Pteranodontia, the "distinctive feature of which as compared with the other Pterosaurıa, is the absence of teeth."

3. If birds with teeth had been known to us at all times, or in the recent state, or in great number and diversity, is it probable that, the entire group having the rank of a class, we should have been led to form two primary groups, the Odontornithes and the Anodontornithes.

4. How would the question appear in case unmistakable evidences of teeth are found in the embryos of recent birds? That such signs will be sometime discovered can hardly be doubted, especially when the embryology of the ostrich is as well known as that of the common fowl. Some are even now of opinion that such structures have been seen. So cautious a compendium as Rolleston's Forms of Animal Life, says: "dental papillæ, with caps of dentine, have been observed in the embryos of Psittacidæ." Since, however, Prof. Marsh holds (p. 13) that the "vascular papillæ seen by St. Hilaire and others were apparently portions of the horny beak," we may consider the point unsettled.

5. May it not be that, in our natural surprise at the

HESPERORNIS REGALIS, MARSH.

unexpected presence of teeth in connection with an otherwise bird-like structure, we have overestimated the true taxonomic significance of the facts, and lost sight, for the moment, of our customs in other groups? May it not be, indeed, that we have been unconsciously affected by the phenomenal nature of most of Prof. Marsh's palæontological discoveries, and that we have not only been unduly impressed by the facts, but also influenced in some degree by the general admiration for the discoverer's achievements, so as to refrain from questioning his conclusions? Yet, as has been shown already, our author has kept his own mind open upon this yery point, and it is to be hoped that he may have the pleasure and the honor of discovering other forms of Aves dentatæ, affiliated in other respects to the several groups of existing birds, and held together only by their teeth.

Hereafter such problems as are involved in this memoir will be discussed more advantageously in the light of the considerations respecting the Evolution and Classification of Vertebrates which have been presented recently by Prof. Huxley.

So admirable is the present work as a whole that one shrinks from any criticism of details. Upon the following points, however, some improvement could, perhaps, have been made:

While insisting upon the lack of bony union of the ends of the mandibular rami in the American Odontornithes, our author makes contradictory statements in regard to the tissue by which they were joined during life. On pages 11 and 179 it is said to have been *ligament;* on page 123, and in the explanation of plate 1, *cartilage* is specified, while on page 112 the union is said to have been "as in serpents." Judging from the appearance of the surface shown in plate 1, fig. 4, the union was ligamentous rather than cartilaginous, but there may have been a mingling of the two kinds of tissue.

The date of the discovery of *Hesperornis* is given as November, 1870, on page 2, but as December on page 195.

It would have greatly facilitated references if there had been given in this volume a complete Bibliography of Odontornithology, together with a statement of the dates of discovery of the various forms, and the dates of their assignment to more comprehensive groups than species and genera. The synonymy as given under the species named in the Appendix does not quite meet this want.

In view of the aid which evolution has received from embryology, it would seem that even a special palæontological memoir like the present might have contained some expression of the author's expectation that light may sometime be thrown upon the problems involved by the careful scrutiny of the development of certain recent birds, notably the Struthionidæ.

B. G. W.

REPORT SUBMITTED TO THE ACADEMY OF MEDICINE ON THE SUBSTITUTION OF MARGARINE FOR BUTTER AND LARD IN THE PUBLIC ASYLUMS OF THE DEPARTMENT OF THE SEINE.—M. Riche finds that pure butter yields a quantity of fatty acids insoluble in water ranging from 86.5 to 88 per cent of the weight of the pure fatty matter, whilst in all the other fats and animal oils, and in almost all vegetable oils, there is from 95.20 to 95.80 per cent of insoluble fatty matter.

ON THE SOUTHERN STARS AND OTHER CELESTIAL OBJECTS.

By J. H. POPE, NEW ZEALAND.

This paper embodies the results of observations made during the last eight years. While most of the work is original, yet, when the object described is important, and an account of my observations could not be satisfactorily given without reference to the work done by previous observers, their facts and opinions have been quoted. An apology is scarcely needed for giving a short *résume* of the facts known about the great star *Alpha Centauri;* accordingly, a very brief history of this remarkable object, from Lacaille's time (1750) to the present has been given.

The instruments used were an 8½ inch reflector, by Browning, and a 4¼ inch equatorial of superior quality. The measures of angles and distances have been obtained by the methods described in my paper in last year's "Transactions."* The angles of position will, I have little doubt, be found to be good, but the atmosphere has not been steady enough of late to admit of the best use being made of oblique transits. I have, however, little doubt that such measures of distances as are given will be found to be very satisfactory approximations to the truth. For the spectroscopic work recorded in this paper I have used an admirable little star-spectroscope, by Browning. This instrument has enabled me to determine, quite satisfactorily, the class to which the stars examined belong, and, in many instances, to say that the spectrum lines of certain elements are probably present. As, however, the means at my disposal did not permit me to make accurate *measures* of the positions of lines, my work in this department should be looked upon as the results, so to speak, of a "flying survey," useful perhaps, in its way, but to be superseded when more thorough and accurate determinations can be obtained.

It should be stated, however, that, while depending on eye estimation alone, it would be very unsafe for an observer to say, that a conspicuous line, for instance, in the greenish blue of the spectrum of a certain star was certainly the F hydrogen line; yet it is unlikely that a practiced eye, one trained to recognize the position of certain lines in spectra that have been already measured, could be mistaken, in any large proportion of cases, in picking out, say, the principal Fraunhofer lines in a stellar spectrum. On the whole, it seems to me that such determinations as are given in this paper are not without a real value, if carefully made. Many years must elapse before the lines in the spectra of the southern stars can be accurately measured by methods like those employed by Dr. Huggins. In the meantime such results as those here given are all that are available. These serve to give us a certain amount of information that can be thoroughly relied on; they enable us to state, further, that the existence of certain physical conditions, and the presence of certain elementary substances in certain stars, are highly probable; and, possibly, they are calculated to create or stimulate in us a desire to learn more certainly and fully the constitution and physical habitudes of the stars.

The objects are treated of in the order of their Right Ascension, and the places of the stars when given, are taken from the "First Melbourne Catalogue," epoch, 1870.

The first star on the list is *Achernar* or *α Eridani.* This fine first magnitude star is very nearly pure white, without any discernable tint, except possibly a slight shade of blue. This star belongs to Padre Secchi's first class of stars, the type of which is the giant sun *Sirius.* In the case of typical stars of this class, the spectrum is

* Trans. N. Z. Inst., Vol. XI., Art. X.

remarkable for the great breadth and distinctness of the hydrogen lines. Indeed these stars are for convenience often called "the hydrogen stars." All of them are white or bluish-white. In *Achernar* the hydrogen lines are not nearly so strongly marked as they are in some others of the class. Indeed the star by no means nearly approaches the type, and is probably to be considered as holding a position between such stars as *Sirius* and stars of the second class, like *Procyon*, though much nearer to the former than to the latter.

π *Eridani.*– This beautiful little double-star is just visible with the naked eye in fine weather. It is about one degree from *Achernar*, north following. The two components are of the same orange color, and of very nearly equal magnitudes 7 and 7. When Sir John Herschel measured this star (anno 1835.0), he found the angle of position with the meridian to be 122.3°. Powell, in 1863, found the angle to be 73.9°. Last week (say anno 1879.75) the angle was 58.8°. The distances for the same dates are 3.65″, 4.88″, and 5.3″. This interesting double is, therefore, very probably a binary star of comparatively short period.

θ *Eridani.*—R. A. 2hrs. 53min. 19.9 secs. Decl. 40° 49′—35′ 17″ S. In the Melbourne Catalogue, the magnitudes 5.2 and 6.2 are assigned to the components of this fine double-star. There is most certainly serious error here. The star is plainly, taken as a whole, a large fourth, or a small third-magnitude star. Probably magnitude 3.9 for the larger star, and 5.9 for the smaller one, would not be far from the truth. The color of the larger star is yellowish-white, with a faint green tinge; the smaller is a light shade of indigo blue. Sir John Herschel's angle of position and distance, in the year 1835.75, were 81.5° and 8.68″. The angle at the epoch 1879.75 is 85.4°. I have not been able to get a thoroughly satisfactory distance, but it is now somewhat over 10″. Time and accumulated observations will, of course, show either that the change in the angle and the distance of the two stars of this double is owing to the proper motion of one, or both, of the components, or that θ *Eridani* is a binary system. The latter alternative appears to me to be by far the more probable.

232 *Reticuli* of the Melbourne Catalogue is a fine star of a magnificent scarlet color. It is of magnitude 6½. There is a distant companion white star of the eleventh magnitude. The R. A. of 232 *Reticuli*, is 4hrs. 35min. 15.15 sec., and the declination 62° 20′ 0.63″ S. The spectrum of this star is very remarkable. It belongs to Secchi's fourth class. The typical star of this division is small—invisible, in fact, to the naked eye; it is variable both in light and color; it is a very distinct red, ruby, crimson, or scarlet; and its spectrum consists of bands of light, sometimes containing faint bright lines with dark spaces between the bright bands. 232 *Reticuli*, though so small, gives a fine spectrum when the spectroscope is used with the reflector, because the light is not spread out over the whole length of the spectrum, but is concentrated in certain parts of it. Thus the red part of the spectrum is very bright, but the place of the orange is occupied by a very thick black "bar." The yellow, again, is pretty bright, and so is part of the green, but towards the violet end of the spectrum the light is very faint, and the colors are quite cut out for large spaces by intervals of almost complete darkness. I failed to notice here what is said to be characteristic of this class of stars—a gradual diminishing blackness of the bars in the direction of the violet end of the spectrum; nor could I distinguish any bright lines in any part of the spectrum. The study and observation of stars of this class is none the less interesting to us, because in the present state of our knowledge their spectra are unintelligible, for it is generally felt by those who have been in the habit of observing them, that there is a great secret of nature waiting to be discovered in connection with them. Their being for the most part so very variable both in light and color, the strongly-pronounced red color of all of them, and their strange and beautiful spectra, all point to the conclusion, that the man who succeeds in "reading the riddle" of the nature and constitution of the red variable stars, will have made a very important contribution to our knowledge of the process by which suns and systems are evolved out of the primordial nebula, or whatever the substance may be, from which such systems are formed, and to which, perchance, when their mission is fulfilled, they again return. In the meantime these red stars seem to set anything, even like rational conjecture, at defiance.

α *Argus* (*Canopus.*)—This great star, the only rival of *Sirius*, is a hydrogen, or first-class star. In its spectrum, the F and C hydrogen lines, and that near G, are broad and distinct, though less so than in the spectrum of *Sirius*. There are a great many very fine lines in the spectrum of *Canopus*, but these are not generally visible. It is only when the atmosphere is very steady and clear that they can be plainly seen. A fine line, however, or rather a small group of lines, in all probability that called *b*, and due to the presence of magnesium in the photosphere of the star, can generally be made out in moderately fine weather.

π *Argus.*—This is a wide telescopic double-star, forming, with a very distant companion of about the fifth magnitude, another double, easily visible as such with the naked eye. The color of the large third-magnitude star is a strongly-marked orange; the other two are indigo-blue. It is a well-known fact, that a large yellow or orange-colored star has frequently a distant companion of a blue or green color. It is generally supposed that this is a sort of *primâ facie* evidence that the two stars are in some way physically connected. It seems to me that the existence of these complementary colors in apparently neighboring stars in no way indicates *per se* that they are physically connected. I am inclined to think that, given a large bright orange star, with a smaller star naturally very white and nearly in the line of sight, this latter must appear greenish or bluish. The light of the bright orange star fatigues the eye as far as its power of receiving the impressions which we call red, orange, and yellow is concerned. Now, when the eye is directed to the smaller star, the less refrangible portion of the light coming from this fainter object is unable to act with its normal effect, while the green, the blue, and the violet rays, by which the eye has not been fatigued at all, produce their ordinary impression.

It is commonly said that this explanation may be true enough in a few cases; but that, if the bright star is hidden behind a thick bar placed across the field of the telescope, and the smaller star still appears blue or green, it is a proof that the light of the smaller star is really blue or green, and that its color cannot be the effect of mere contrast. This is, I feel sure, fallacious. I have often tried the experiment and at first it was very disappointing, for one would naturally expect that a star, which appeared colored in the presence of a very bright companion, would show its color still more distinctly when that companion was hidden from view. But this never happened, the more completely the light of the larger star was removed, the less was color in the companion observable. I feel persuaded that, if the light of the larger star could be entirely cut off, which, by-the-by, is impossible, the blue color would entirely disappear. It is worth noting, too, that the longer one looks at a blue star, its companion being hidden, the more completely does the blue color disappear; that is, I take it, as the eye recovers its normal condition, after being exposed to a severe strain from the light of the large star, so does its sensitiveness to the feeble red, orange, and yellow rays of the small star return, and it sees the small star to be white or nearly so. On the other hand, I have often noticed that the longer one looks at a double star of this kind, both stars being in the field, the more pronounced does the blue become. There is only one instance, that I am aware of,

in which this theory will not hold good. The small companion of *a Scorpii* is undoubtedly really greenish. I saw it on the 23rd of March, 1878, emerge from behind the moon after an occultation while its bright companion was still hidden, its color then was a pale pea-green. There could have been no contrast here, except with the moon's light; admitting this exception, however, it seems to me highly probable that while, in such wide double stars as *π Argus* and *γ Crucis* the orange or yellow star is really what it seems, the star that appears green or blue is, *as a rule*, really white. If this view is the correct one, it follows that those observers who spend a great deal of time in observing the tints of the companions to large stars, are, to a great extent, wasting their time.

γ Argus.—This fine second-magnitude multiple-star has a very curious spectrum. It belongs to a very small class of stars, the only other one that I have heard of is in the Northern constellation *Cassiopeia*. In the spectrum of *γ Argus* there are certainly three very *bright* lines, one rather faint, and, I believe, many finer ones. I am almost certain, too, that there are several fine dark lines in the spectrum. The brightest line is, not improbably, the F hydrogen line; and the somewhat fainter one, the C hydrogen line. Of the other two very distinct bright lines, one is certainly not very far from the position of the D sodium line; but I cannot place the other. The presence of bright lines in the spectrum renders it far more difficult than usual to estimate the positions, but the other line seems to be about one-third of the distance from D towards the iron line E. Not improbably then, outside the photosphere of *γ Argus*, there are ever-present enormous masses of hydrogen and sodium, as well as other substances in the gaseous condition, which have been ejected from the more central parts of this sun; and, the temperature of these incandescent gases being much higher than that of the solar photosphere below, their spectrum is super-imposed on the ordinary spectrum of the star proper.

ε Argus.—This yellow star belongs to Secchi's second class. In these stars the lines are very fine, and not easily seen unless the weather is very favorable. To this class our sun belongs. In the spectrum of *ε Argus* the F line can be seen pretty easily, but the D sodium line seems to be the most distinct of this spectrum.

β Argus.—Magnitude, one and a-half. Color, white. A first-class star. The hydrogen lines are pretty broad and distinct.

The blue Planetary Nebula near the Southern Cross.—This object, No. 3365 in Sir John Herschel's Catalogue, is in R. A. 11hrs. 44m., and decl. 56° 31′ S. The color of this strange object is a bright unmistakable blue. This nebula, like other planetary nebulæ that have been examined in the Northern Hemisphere, gives a spectrum of one bright line. Possibly, in a larger instrument, more lines might be seen. It is, of course, impossible with my apparatus to determine the position of this line, as there are no landmarks, so to speak, to guide one to a decision. It is most probable, however, that it is one of the hydrogen or of the nitrogen lines, and that this planetary nebula is a spherical mass of one or both these gases in an incandescent state.

a Crucis.—This superb *pair* of stars, by far the finest in the sky, consists of two stars, bluish white in tint, and very nearly equal in size, each being of the second magnitude. There is a distant six-magnitude companion, of a sea-green color, as well as three smaller comites of magnitudes, 12½, 14, and 13 respectively, These latter are well seen in the 8½-inch reflector, but a small telescope of course does not show them. I have made a very great number of measures of the angle of position of this star, and having weighted the observations with reference to the state of the atmosphere, etc., at the time when the measures were taken, I find the angle of position for the year 1878.7 to be 118.5°. This by a very singular coincidence, is exactly the same angle as that obtained by Powell in the year 1863. Herschel gives the angle for 1835.33 as 120.6°. I may say that, if I had rejected two of my observations, which were made in rather bad weather, and which exceeded the average of the rest by 1½° and 3½° respectively, the angle obtained, taken in connection with Powell's and Sir John Herschel's, would have indicated, I believe, a very slow but really regular angular motion, in a retrograde direction, since Herschel's time, and would, with the measures of distance given below, have convinced me, at all events, that *a Crucis* is a binary star of very long period. The temptation in such cases to "cook one's accounts" a little to omit taking into account facts or numbers which do not square with one's own views or wishes, is very strong, but the man who cannot resist it had better give up science altogether and take to something else in which it is not of vital importance that he should tell the truth, the whole truth, and nothing but the truth, with regard to his observations. The distance between the two stars at the epoch, 1836.36, was 5.65″; in 1863, Powell made it 4.98″; and at the end of last month, 1879.75, the distance, a mean of several measures, was 4.79″. *a Crucis* is a hydrogen star, but its spectrum is very difficult to observe, except in the finest weather. Even then the only lines that I can make out are the hydrogen lines, and they are by no means very easy to see.

γ Crucis.—It has been customary for astronomers to catalogue this star—the "Head of the Cross"—as a double star; but the proper motion of the large orange-colored star is rapidly carrying it away from its five-and-half-magnitude blue companion. The spectrum of *γ Crucis* is perhaps the finest of all stellar spectra. The groups of lines are so numerous and so well marked that this spectrum may be observed under almost any atmospheric conditions, if the star can be seen at all. *γ Crucis* is a typical star of Secchi's third class, which are all orange color verging towards red. In their spectra there are numerous, easily-seen, close groups of lines; but the hydrogen lines are either very indistinct or altogether absent. *a Orionis* and *a Herculis* are good specimens of the two principal subdivisions of this class. In the spectrum of *γ Crucis* there are at least eight broad groups of lines, and some of these occupy the parts of the spectrum at which sodium, iron, magnesium, and calcium lines are found in the solar spectrum. But, because they are groups, it is much more difficult to say whether they contain the lines belonging to those elements or not, than it is in the case of a first or second-class spectrum. Still, I anticipate that careful measurements will confirm my opinion that iron and magnesium lines, especially the latter, are present in the spectrum of this star; the sodium line is probably there too, There is, also, a fine line just at the part where the green merges into the blue of the spectrum. This is possibly the F hydrogen line.

There is one very significant feature in this spectrum, so at least it seems to me. It is well known that when the Sun is near the horizon, especially in damp weather, his spectrum contains certain groups of lines which are due to the aqueous vapor in our own atmosphere, and that, as he reaches a greater altitude, these lines become faint or disappear. Now, two at least of the groups in the spectrum of *γ Crucis* appear to occupy the same position as two of the principal groups of atmospheric lines. Now this being verified, important conclusions might follow. Secchi, on grounds of this sort, infers the existence of aqueous vapors in the neighborhood of sun-spots. The Spectroscope knows nothing, so to speak, about distance, except indeed where motion of approach or recession is concerned. If these aqueous vapor-lines are produced in spots on the sun, may they not be produced in much the same way in *γ Crucis*, the principal difference being that on the distant star the cause is more general and the effect greater than it is on our own Sun. If I am not mistaken, the existence of these spectrum lines should enable us to read a certain portion of the "life history" of a star.

This history might be something like this: Let us suppose that, countless ages ago, *γ Crucis* was a white star, like *Sirius*. It was then far more intensely heated than it is now. All the elements of which it is composed were there uncombined. Hydrogen, the gas of the smallest density, ordinarily extended furthest from the centre of the globe, and this hydrogen, its outer envelope, was nearly always near the confines of the normally cold regions of space. Thus it would have a somewhat lower temperature than the rest of the sphere, and hence well-marked hydrogen lines would appear in its spectrum at this period. Comparatively small quantities of other elements, however, would frequently be erupted from the interior portions of the sphere, and would reach what may be called the surface. The presence of these would cause the appearance of numerous fine lines in the spectrum. As eternity went on, if I may use the expression, the star radiated a large portion of its heat into space, the elements began to combine chemically to a certain extent, large volumes of hydrogen ceased to exist as such, through combining with oxygen and forming water-vapor, of which the outer star envelope would now consist. In place of the hydrogen lines of the white star therefore, we now find the aqueous vapor spectrum—"the atmospheric lines" as they are called. The result of the combination of the oxygen and the hydrogen would, of course, be a great decrease in the volume of the outer envelope. This would probably bring the lines of sodium, magnesium, iron, and calcium into greater prominence, and we should have the spectrum which *γ Crucis* now presents. Between the two conditions described there would be an intermediate one. Through such a stage our Sun may possibly be passing now. It may be, in short, that our Sun was once a *Sirius*, is now a *Procyon*, and will by-and-by be a *γ Crucis*. This is a mere hypothesis, of course, though it appears to account pretty fairly for some of the phenomena of the stars. In fact, I give it merely as a suggestion, feeling that it is as little entitled to carry weight with it as an hypothesis, founded on observed phenomena and not at variance with known facts, can be.

γ Centauri.—R. A. 12hrs. 34min. 21.46secs. Decl. 58° 14′ 43.24″.—This is a very fine close pair of stars, each component being of the fourth magnitude, and purely white. In his "Results of Observations at the Cape of Good Hope," Sir John Herschel gives the position-angle as 354.3°, the epoch being 1835.89, while the distance is stated to be ¾″. To this estimate of distance Herschel attaches no value. For the year 1878.93 the angle of position is 6.6°, or 186.6°, and the distance 2.2″.

β Crucis.—This fine white star has a distinct deep blood-red companion, the position angle being 260½° and the distance (1879)–208″. It seems to me that the small star varies in size from about the eleventh to nearly the eighth magnitude. It would be well if the small star could be watched, so that its period and the amount of its variation in brightness might be accurately ascertained.

α Centauri.—R. A. 14hrs. 30min. 47.07secs. Decl. 60° 17′ 53.93″. Magnitudes, 1-2. The following table will give the position-angles, and the distances of the components of this star, for selected epochs during the forty-five years which have elapsed since 1834, when it was first accurately measured by the greatest of all astronomers, Sir J. Herschel:

Observer.	Date.	Position.	Distance.
Sir J. Herschel	1834.7	—	17.43″
Sir J. Herschel	1834.8	218° 30′	—
Sir J. Herschel	1835.7	219° 30′	—
Sir J. Herschel	1837.3	220° 42′	—
Sir J. Herschel	1837.4	—	16.12″
Pcwell (from Webb)	1864	5° 7′	7.85″
Computed from mean places in F. M. G. C.	1870.0	17° 19′	10.73″
My recent measures	1878.7	156° 19′	—
My recent measures	1879.75	183° 8′	4.55″

With this table as a basis, it will be found that the major axis of the apparent orbit lies nearly in the direction 26½° to 206½°, and that the greatest elongation north is about 11″, while the greatest elongation south is 27″. Mr. Powell makes the period between 76 and 77 years. If the places of the two stars given by Lacaille (1750) were correct, however, the period would be just about 85 years, for the angle of position computed from his places of the stars is 218° 44′, which a reference to the above table will show, was very nearly Sir John Herschel's micrometrically-determined position 84.79 years afterward. As, however, the *distance* obtained by Sir John Herschel disagrees very materially with that deduced from Lacaille's places of the stars, but little weight is attached to the observation of 1750.

This magnificent double star is the finest object of the kind in the heavens. Besides being a binary star of very short period, every one knows that *α Centauri* is our next neighbor among the stars, and that it was the first to give up the secret of its parallax under direct Transit Circle observations. The color of this star is straw-yellow, or sometimes golden-yellow, according to the state of the atmosphere. When there is haze, of course the smaller star is somewhat more affected by it than the larger. This tends to give it a slight brownish tint when the sky is not clear. *α Centauri* is a star of the second class. Its spectrum is very like that of the sun. Even the principal dark lines are fine, and they apparently occupy the same relative positions as do the well-known lettered lines in the solar spectrum.

The resemblance between the two spectra is so striking that any one seeing the two spectra for the first time could hardly fail to notice the similarity. More dispersive power, however, and the means of accurately determining the position of the lines of *α Centauri* might show that they are not the same as the solar lines. Such a result would surprise me much. The D sodium line, the E iron line, the *b* magnesium line, and the F hydrogen line of the Sun have, almost certainly, their counterparts in the spectrum of *α Centauri*. There can be little doubt that the physical constitution of this great star is, in most respects, the same as that of the Sun. It is probable, however, that *α Centauri* is less developed than the Sun; for, as Mr. Proctor has pointed out, its light is brighter than its mass would lead us to expect it to be, judging from the light of our Sun, as compared with his mass. While the mass of the star is to the mass of the Sun as 2:1, the light of the star is to the light of the Sun as 3:1. Now, if it is true, as physicists have good grounds for believing, that the Sun is, and has been, very slowly but surely losing his heat, just as our earth has most certainly lost an enormous amount of hers, there must have been a time when the Sun and his system were less developed, but far hotter and brighter than they are now—when they formed, probably, as I said when speaking of *γ Crucis*, a white star—that is to say, there was, quite possibly, a time when the light from our Sun bore the same relation to his mass as the light from *α Centauri* bears to its mass. We may also believe that matters are less advanced in the planets (if there are any) of this neighboring system than they are with us.

α Trianguli.—The spectrum of this star is not very striking, but it is rather curious, as showing, apparently that the star is in a condition intermediate between that of *α Centauri* and that of *γ Crucis*. The lines of the second class, and also the groups, are very faint, but they are there. It will be seen that this fact has some bearing on the suggestion I made respecting the gradual development of stars while speaking of *γ Crucis*. Here it looks as if we had, so to speak, caught a star in the act of changing from the second to the third class. What I have seen of the spectra of the stars, so far, leads me to think it probable that if every star, down to the sixth magnitude, could be examined even with my instrument, and mapped roughly, it would be found that the spectra

obtained could be so classified that a series might be made, each member of which would differ from the next almost insensibly. This, of course, would take a long time to do, as small stars can be examined only in very fine weather. When it was done, however, the results would be very valuable and interesting.

α Gruis.—This is a second-magnitude white star, with the usual spectrum crossed by distinct hydrogen lines.

β Gruis is a second-magnitude star, and nearly as bright as the *lucida* of this constellation. Its color is reddish-orange, and its spectrum is much like that of *γ Crucis*, but the groups of lines are not so distinct, and, generally, there is a sort of approach to the appearance presented by the spectrum of *Mira Ceti*, which I find thus described in my note-book, under the date October 8th, 1878: "Saw to-night the spectrum of *Mira:* it is really wonderful—something like that of *α Herculis*, as given by Chambers. It seems to consist of bright broad bands, with narrow ones in between. These bands are dark, but hardly black. The effect produced is, as it were, that of an irregular set of columus. The brightest part of the spectrum is at the yellow and the green."

α Piscis Australis (*Fomalhaut*).—This star is visible at home sometimes, but its altitude there is so small that it can scarcely be properly observed with the spectroscope. *Fomalhaut* is a first-class star of the most pronounced type; it is very remarkable for the great breadth of the F hydrogen line. In *Fomalhaut* it is far broader than it is even in *Sirius*. As an increase in the breadth of the hydrogen lines has been shown to be due to increased pressure, and as the increase in breadth is also proportional to the pressure brought to bear upon the gas which gives the lines in the spectrum, we may, I would venture to suggest, conclude that the pressure at the surface of this star is extremely great. That is to say, *Fomalhaut* is either extremely dense and compact, so that its radius is very small compared with its mass (which is not very likely), or it is one of the very largest stars in the sky.

In conclusion, I would ask you to overlook any faults of style that may be observable in this paper. It claims to be nothing more than its title announces it to be—"Notes on Southern Stars."

SCIENTIFIC BOOKS.

Mr. W. H. Farrington recently gave an interesting Lectures on scientific books before the American Institute, a full report of which may be found in *Engineering News* of March the 19th. He said that in spite of the large number of scientific works published, there still are constant enquiries for books on certain subjects, which have yet to be written. This he explained was due to various causes, one being that the demand for certain books do not warrant their publication, and secondly, that many works treating on manufactures are withheld, it being the policy of those who could write them, to keep from the public such information. He stated that the English publishers seldom stereotype their better class of books, but print from the type, whereas in America it is the custom to print from such plates, permitting a much smaller edition to be issued. Those interested in the literature of Mechanics, and "*Engineering Science*," should read Mr. Farrington's Lecture from which they may gather many practical hints respecting the purchase of such books.

ASTRONOMY.

THE March number of the *American Journal of Science* contains a paper by T. C. Mendenhall, of Tokio, Japan, 'On the Determination of the Coefficient of Expansion of a Deffraction Grating by Means of the Spectrum." The object of the research was to find the coefficient of expansion of the peculiar alloy of tin and copper, now generally used for ruling gratings. The value of the coefficient of expansion is independent of the wave-length of the line upon which the measurements are made and of the number of lines to the inch. The temperature of the grating was altered by placing the plate in one end of a small wooden box which could be filled with water and brought to any given temperature. The resultant value for the coefficient of expansion from the mean of twenty measurements is

$$E = .0000202$$

DR. MEYER, Assistant Astronomer at the Geneva Observatory, has employed the microphone in transmitting the beats of the standard clock of the Observatory to different parts of the building, and also to the Regulating Clock of the city Time Service. The microphone is fixed upon the outside of the clock-case and placed in circuit with a small battery and a telephone. The beats of the clock can then be readily heard throughout the room.

AT the request of the Treasury of the Royal Astronomical Society, a committee has been appointed to advise the Government upon the steps which it is desirable to take in order to secure observations of the Transit of *Venus* across the sun's disk, 1882, December 6. The committee—which consists of the Astronomer Royal, the President of the Royal Astronomical Society, the President of the Royal Society, Professor J. C. Adams, the Earl of Crawford and Balcarres, Dr. De La Rue, Dr. Huggins, Professor H. J. S. Smith, Professor Stokes and Mr. Stone—has already commenced its labors.

ABOUT a year ago Admiral Moucher asked for a credit of 4,000 francs per year in order to publish a monthly astronomical review. M. Jules Ferry refused the grant, but a similar review is now being published at Brussels under the name *Ciel et Terre*. It appears twice a month and is devoted to meteorology and astronomy.

THE second number of *Urania* contains quite an elaborate article by H. C. F. C. Schjellerup, entitled, "Recherches sur L'Astronomie des Anciens;" also a short communication upon Observations of the Spectrum of Comet 1880 f. (Pechüle) at Dun Echt, and a "Circular from the Smithsonian Institution."

A NEW VARIABLE STAR.—M. N. C. Dunér, of the Lund Observatory, reports upon the 24th of February, 1881, the discovery of a new, small variable. The star is given in the Bonn Durchmusterung (1855.0)

9.4 mag. R. A. $= 5^h, 17^m, 32^s.7$.
Dec. $= + 34^\circ 2'.1$.

THE asteroid, No. 217, discovered by Coggia at Marseilles on the 30th of August, 1880, has recently been named "*Eudora*."

WASHINGTON, MARCH, 1881. W. C. W.

We are informed by Professor Davidson that the following is the correct geographical position of the Davidson Astronomical Observatory, San Francisco, Cal.:

Latitude $= 37^\circ 47' - 22''.3$ North.
Longitude $= 122^\circ 24 - 39.0$ West of Greenwich.
In time $= 8^h 09^m 38^s.6$

This differs from the figures we recently gave at page 107, in the number of seconds in time.

BOOKS RECEIVED.

THE TELESCOPE. By THOMAS NOLAN, B. S. D. Van Nostrand, 23 Murray Street. New York, 1881. Price 50 cents.

This little handbook presents very briefly the principles involved in the construction of refracting and reflecting telescopes, illustrated with about thirty diagrams. For an amateur desirous of following Herschel's example of making his own telescope, this work will be found a practical guide. We notice the author gives the form of object glass suggestod by Messrs. Alvan Clark & Sons, the noted makers of astronomical object glasses. They say "many forms may be used, but from our experience, we have found that to *make the crown glass lens of equal curvature, and the flint glass lens nearly flat on the side next the eye*, is the most convenient, and *gives as good results as any other form.*

MICROSCOPES.

The *American Journal of Microscopy* for March is an excellent number full of interesting matter and two full pages of illustrations.

We notice Professor Phinn corrects a statement mentioned in Journal of R. M. S. that 80,000 to 100,000 diameter were within the power of his appliances. He now gives as the limit of amplification of a high angle objection, say, an object of one tenth, and a one eight eyepiece, 8,000 to 10,000 diameters. We notice in another part of the Journal that Professor J. Edwards Smith obtains 8,000 with the same-eye piece and a 1/6 object.

Dr. E. Cutler describes a flagellate infusorium called *Asthmatos Ciliaris*, which occurs in connection with one form of contageous cold coryza or influenza. These parasites may be easily detected in the early sneezing stage, the nose runs and the eyes water; they are located in the anterior nasal passages, on the mucus membrane of the conjunctiva of the eyes, and of the pharynx and larynx. Simply transfer a drop of the thin mucus to a slide, cover, then examine with a good 1-5th and 1 inch occular.

There appears to be confusion as to the classification of this parasite, and as the opportunity for studying it will probably be oftener than agreeable, we shall be glad to hear from any of our readers who throw light on the subject.

Dr. F. L. Bardeen considers that wax cells have been too hastily abandoned by their originator, Professor H. L. Smith, who fully described them in "SCIENCE." Dr. Bardeen says that if prepared as he suggests, they are the best cells for opaque mounting.

Dr. A. C. Stokes has an excellent paper on "Growing Slides," and treats the subject in a most exhaustive manner; as most of the contrivances can be made by the microscopist, this article will be of the greatest benefit to this class,

Dr. Smith Baker, in a paper on the "Microscopal uses of the Cat," offers a plea for the more universal use of this domestic animal in microscopical study.

In view of the advice offered by Professor Burt G. Wilder, in regard to the use of the cat by anatomists, and the increasing disposition of students to use the cat for such purposes, we fear that this genus will soon be at a premium.

MANURIAL EXPERIMENT WITH SUGAR BEETS. — Phosphoric acid, applied preferably in the spring, increased the yield of sugar most decidedly.—M. MARCKER.

OCCURRENCE OF VANILLA IN RAW SUGARS.—The authors have succeeded in isolating small quantities of vanilline from crude-sugar.—E. v. LIPPMAN and Prof. C. SCHEIBLER.

THE GLYCERINE BAROMETER.

Mr. James B. Gordon has published the following description of his glycerine barometer—which appears to have at least one advantage in being easily read off, as the usual tenth of an inch on the mercurial barometer is represented in the glycerine barometer by something more than an inch; thus the changes which take place are rendered obvious even to an unpracticed eye.

Our readers may have heard of Daniell's water barometer, which was destoyed in the fire at the Crystal Palace in 1866. Mr. Jordan constructed another, which has since continued in operation. In the course of his experiments on various fluids, he was led to try glycerine, which appears well adapted for the purpose. Its vapor has a very low tension at ordinary temperatures, and as its freezing-point is much below zero, it is, so far, excellently adapted for use in barometers. The mean coefficient of expansion by heat is, according to Professor Reinold, .000303 for a degree of Fahrenheit's scale, and a table has been computed on this basis for reducing the observations to 32° Fahr. Glycerine possessing the capability of absorbing moisture from the atmosphere, its surface in the cistern is covered by a layer of mineral oil, which has no effect whatever on the glycerine, and which does not evaporate at ordinary temperatures. At sea-level the pressure of the atmosphere supports a column of glycerine of a mean height of 27 ft., and accordingly the tube of the barometer is made some 29 ft. in length. It is formed of composition gas-pipe, ⅝ths of an inch in diameter, but the upper part, 4ft. or so in length, is of glass tube, having an internal diameter of 1in. The top end, instead of being sealed, is spread out into a cup-shape, having a small orifice plugged with a stopper of rubber. The cistern is of tinned copper 4in. deep and 10in. in diameter, and the air is allowed to press on the surface through a small hole leading into a chamber containing a filter of cotton wool. At the bottom of the cistern is a closed channel opening into the centre, and to this is attached a projecting vertical tube, to which the main tube is soldered. The object of this channel is apparently to provide a means of closing the tube by a screw-plug when refilling is necessary. The quantity of glycerine required for such an instrument is about a gallon, and this being warmed in a water-bath and tinted with rosaniline, sufficient is poured into the cistern to cover the orifice of the channel. The plug at the top end is then removed, and the tube completely filled by pouring the glycerine gently down one side. After allowing it to rest for some time, the air bubbles will be found collected at the top, when the tube is again filled up to the cup, and the stopper replaced. The screw-plug in the cistern being removed, the column will fall until balanced by the pressure of the atmosphere, and the vacuum is as perfect as it is possible to get it, the small quantity of glycerine remaining in the cup above the stopper hermetically sealing it. The glycerine barometer is therefore a simple and easily managed instrument; but it is not pretended that it can take the place of the standard mercurial instrument for precision. It is comparatively a new instrument, and its value as a piece of scientific apparatus has yet to be shown.

HYDROBROMIC ACID AS A REAGENT FOR COPPER.—A drop of the solution in question is placed in a watch-glass, a drop of hydrobromic acid is added and the mixture evaporated at a gentle heat. When it is reduced to the bulk of one drop a rose-red coloration appears, three or four times more intense than that produced by potassium ferrocyanide. In this manner 1-100th milligrm. copper may be detected.

DETECTION OF METHYLIC ALCOHOL IN VINIC ALCOHOL.—MM. Cazeneuve and Cotton propose as reagent a solution of potassium permanganate containing 1-10th per cent of the dry salt. The permanganate at ordinary temperatures is reduced slowly by vinic alcohol, but instantaneously by methylic alcohol. If to 10 c.c. of alcohol at 20° there is added 1 c.c. of the permanganate solution, twenty minutes are required before the liquid takes the yellow tint indicating complete reduction. If 10 c.c. of alcohol are used containing 1 c.c. of methylic alcohol the yellow tint is instantly obtained with potassium permanganate.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

SATURDAY, APRIL 9, 1881.

UNIFORM TIME.

The question of the introduction of uniform standard time into daily use, for both popular and scientific purposes, having been examined by the American Metrological Society, the president, Prof. F. A. P. Barnard directs attention to the following considerations, and invites exchange of views upon this subject.

He says "local time," in the astronomical sense of this term, varies with every change of meridian; it can therefore not be conveniently retained by travellers, and transportation and telegraph companies, which adopt whatever meridian may be the most convenient Over seventy such standard meridians are now in use by railroad and other companies throughout the United States and Canada; the larger towns and cities frequently adopt their own special local times, and the smaller ones adopt the railroad times most convenient to them; there are thus now in ordinary use at least 100 local times or meridians, many of them differing but a few minutes from each other.

Professor Barnard believes that a more thorough uniformity of accurate time would be to the daily advantage of all members of the community and all business transactions, and would immensely facilitate the study of certain natural phenomena, such as tornadoes, auroras, earthquakes, meteors, &c., for the observation of which we must depend largely upon those who chance to be favorably located.

It is accordingly proposed that the community unite upon a division of this continent into a few sections, throughout each of which the times adopted by railroad, canal, steamboat and telegraph companies, the city or town clocks and the clock makers, shall all be kept as nearly as possible in agreement with one standard meridian.

The system that especially commends itself for adoption, is that which also has the best prospect of being ultimately adopted by all nations throughout the world. It requires that, for the United States, we should adopt a central meridian in the Mississippi Valley, exactly 90° or six hours west of Greenwich, and proceed to the east or west by steps of exactly one hour each, so that the sectional times would be about as in the following schedule.

We have already given attention to this subject, and in "SCIENCE," Vol. I. p. 13, will be found some excellent suggestions in regard to "Uniform time," by Professor Ormond Stone.

In this article we merely present the views of Professor Barnard, the President of the American Metrological Society, and reserve a fuller consideration of the same for a future occasion. We may state, however, that we are heartily in accord with the object Professor Barnard has in view, and are pleased to find the matter in such able hands.

PROPOSED SCHEDULE OF STANDARD TIMES.

Geographical Section.	Standard Meridian west of Greenwich.	Standard Time slower than Greenwich.	Standard Time Slower or Faster than True "Local Times."	Designation of Proposed Standard Time.
Newfoundland New Brunswick Nova Scotia	60°	H. M. S. 4. 0. 0.	29 minutes slower than St. Johns, N. F. 24 " faster than St. John, N. B. 14 " faster than Halifax, N. S.	Eastern Time.
Canada Maine to Florida. Ohio to Alabama. Lower Lakes.	75°	5. 0. 0.	15 " slower than Quebec 18 " faster than Toronto 16 " slower than Boston 3 " slower than New York 8 " faster than Washington 19 " faster than Charleston 45 " faster than Montgomery 14 " faster than Buffalo 30 " faster than Detroit 28 " faster than Cincinnati	Atlantic Time.
Mississippi Valley Missouri Valley Upper Lakes Texas	90°	6. 0. 0.	0 " faster than New Orleans 1 " faster than St. Louis 12 " faster than St. Paul 18 " faster than Kansas City 19 " faster than Galveston 10 " slower than Chicago	Valley Time.

HOW TO OBTAIN THE BRAIN OF THE CAT.

Felis domestica.

BY PROFESSOR B. G. WILDER, M.D.

In the first number of "SCIENCE," under the title "A Bit of Summer Work," the writer suggested that teachers and students of the several sciences in which an acquaintance with the brain is required should try to gain some definite and personal knowledge of the organ by the preparation and dissection of the brain of the domestic cat.

The publication of the article was followed by numerous expressions of a desire to adopt the suggestion, but accompanied often by requests for reference to some work containing explicit directions as to the best methods of manipulation.

No such work is known to the writer. The "Dissector's Guides" and some general treatises on Human Anatomy give more or less complete instructions for the removal of the human brain: but the conditions are usually such that the most expert manipulator can hardly avoid some injury to the organ.[1]

For the removal of the brains of the lower mammals, no adequate directions have been published, so far as the writer is aware, although Chauveau enters (A, 716)[2] into some detail with regard to the horse's brain. Straus-Durckheim expressly states (B, I, 321) that the method for animals is the same as that for the human subject, and the "Practical Physiology" (Foster & Langley, A, 215) contains merely the caution that "the brain of the dog or sheep should be removed from the skull as carefully as possible, especial pains being taken to cut the internal carotid arteries and the cranial nerves close to the skull,"

As guides to practical work for beginners in anatomy, the works just mentioned may, in respect to the brain, be likened to some "Manuals for Young Housekeepers," whose accomplished authors seem to realize neither the inexperience of their readers nor the possibility of conditions very different from their own, and whose teachings, therefore, prove ill-suited to the comprehension and the circumstances of those whom they desire to assist.

Now it is probable that few readers of "SCIENCE" have had the benefit of a full medical education, and it is certain that the anthropotomical method for the extraction of the brain does not answer for the removal of the brains of most other mammals. The skulls are usually so irregular in outline that the use of the saw is difficult and apt to do injury to the brain; moreover, at least for the purposes of preliminary study, the integrity of the brain should be ensured even when it involves the complete destruction of the skull.

The writer is therefore led to hope that the number of those who desire to obtain and dissect the brain of the cat is large enough to warrant the publication in "SCIENCE" of the directions which are followed by the students in the Anatomical Laboratory of Cornell University. Any criticisms or suggestions will be thankfully received. The method here described in detail is to be preferred when the brain is wanted entire, and especially when the length of the nerve roots is an object. The more expeditious methods which may be adopted under other conditions will be described hereafter.

INSTRUMENTS AND MATERIALS.—Medium scalpel;[3] sharp scalpel; arthrotome; tracer; curved scissors; bone-scissors; forceps; nippers; a cat's skull; large tray for the cat; small tray, or a folded cloth, for the head; block; small towel, or piece of muslin, for aiding the grasp of the head; paper for scraps; basin and towel; dish of 7 p.c. brine, about 6 cm. deep, and 20 wide, containing some well-soaked cotton; bowl of normal saline solution (15 grains of salt to 2000 cc. of water) sufficient to cover the head after its separation from the body; bowl for catching the blood; wide-mouthed jar or covered dish, of 60-70 p.c. alcohol, with some well-soaked cotton at the bottom.

Some of these items need explanation. The *arthrotome* —sometimes called "disarticulator"—is a short and strong double-edged scalpel, with a steel handle like that of the common "cartilage knife." The same use can be made of any short strong scapel ground down so as to have two edges of only moderate sharpness. Such an instrument saves the keener and thinner edges of the ordinary scalpels. The *tracer* looks something like the ordinary dental excavator, but its end tapers to a blunt point, which is so curved as to form about the quarter of a circle, and moderately sharpened on the concavity. This is used for tracing and isolating nerves and vessels, and is not only safer than the scalpel, but less liable to injury. Its cost is only 25 cents. The *bone-scissors* are simply a strong pair of curved scissors, employed for comparatively rough work. The *nippers* here referred to are the "diagonal side-cutting pliers" of the dealers in hardware. Instead of being parallel with the handles, as with most "bone-nippers," or at a right-angle therewith, as with the ordinary "cutting-pliers," the blades of these form with the handles a very open angle, confering upon the user an advantage similar to that which is gained by the employment of curved scissors. The nippers are to be had of seven sizes, from 10 to 20 cm., (4 to 8 inches) in length, and cost from 70 cents to $2.25, according to the size and the maker, those of Stubbs being the more expensive and highly finished. For use upon cats, those which are 5 inches long are to be preferred, and their points, if too wide, may be ground off.

The writer has been accustomed to use the nippers since 1872 for the removal of the brains of cats, dogs and young human subjects. It was not until after the year mentioned that he noted, in Flower's paper (3, 194), a remark as to "clipping away the skull from the brain of a monkey," the instrument, however, not being specified.

The nippers are equally applicable to living animals; with the rabbit, cat, and all but the larger dogs, the skull may be penetrated with them, and the opening easily enlarged to any extent desired. Perhaps the surgical "bone-forceps" have been employed for this purpose, but the "Hand-book for the Physiological Laboratory" (Sanderson, A, 305 and 418), directs that even so thin a skull as the rabbit's should be removed with the trephine and the scissors, and Dalton's recent paper (2) mentions only the trephine for exposing the brain of dogs.

Alcohol of the proper strength is readily prepared by adding 1 part of water to 2 parts of 95 p. c. alcohol. According to the size of the bowl or jar, the amounts may be 100 and 200, or 150 and 300 cc.

For the hardening and temporary preservation of the brain, the common deep finger-bowl is convenient. It may be covered with a piece of window-glass. Flat-bottomed dishes, with wide edges ground for the reception of covers, are made by Messrs. Whitall, Tatum & Co., of New York and Philadelphia, and the same firm have on hand wide-mouthed vials and specimen-jars of many sizes.

KILLING AND BLEEDING THE CAT.—When the brain is to be studied the animal should not be "pithed," on account of the injury to the medulla, and the settling of blood at the base of the organ. The cat may be drowned, but the following method is to be preferred as less distressing, more convenient, and permitting the evacuation of most of the blood. The *bleeding* may how-

[1] The writer has employed a modification of the ordinary method, and will take an early opportunity of submitting it to other anatomists.

[2] The system of references adopted in the present paper is the same as that described by the writer in No. 38 of this journal, p. 122, excepting that the numbers of papers published since 1873 are in smaller type than those of the papers which appeared prior to that date, and which are included in the "Royal Society Catalogue."

[3] Cases of dissecting instruments containing the arthrotome, tracer, scalpels of three sizes, curved scissors, forceps, fine-pointed forceps and curved scissors, and blow-pipe, are sold by Messrs. Codman & Shurtleff, of Boston, for $9.00. The nippers and bone-scissors must be obtained separately, as will be explained presently.

ever, be dispensed with. Put the cat in a close box, little larger than itself, and pour in 5 cc. of chloroform, or 20 cc. of ether. It usually becomes quiet in from 5 to 15 minutes. When touching the conjunctiva causes no winking, remove the cat to the large tray. Bring the head and neck nearly into line with the trunk. Part the hair upon the neck along a line between the angle of the mouth and the convexity of the shoulder. Along this line, divide the skin for 6—8 cm., opposite the larynx. This will either expose the *Vena jugularis* at once, or permit it to be seen when the borders of the skin are raised.

With the tracer, separate the vein from the adjoining parts for about 1 cm., and pass a bit of string entad * of it. Then turn the cat on the side, with the exposed vein over a bowl; the string makes it easier to pass the scalpel or blade of the scissors entad of the vein, which may then be cut. Let the blood flow into the bowl, occasionally lifting the body so that the blood may come more readily from the abdomen.

When the flow ceases, replace the cat in the box, with an additional 5 cc. of chloroform, or leave it upon the tray, and apply the chloroform upon a towel held very closely at the nostrils so as to prevent access of air. Death usually ensues in a few moments. If it be desired to ascertain the weight of the entire animal, the blood should be weighed.

If the more delicate internal parts or the microscopic structure are to be studied, the remaining operations for the procurement of the brain should be performed within 24 hours. But if the specimen is desired only for the fissures or the coarser anatomy, removal may be deferred for a week, provided the head be kept in a cool place. It should not, however, be allowed to freeze.

Separation of the skull.—Connect the angle of the mouth with the incision already made. If the sk n is to be mounted, this should be the only incision, and the skin must be dissected from the mandible as well as from the rest of the head. But if, as is more often the case, the skin is not to be preserved, while the muscles etc., of the neck are to be examined, make a corresponding incision from the angle of the mouth upon the opposite side.

In all subsequent operations, unless otherwise stated, both sides are to be treated alike.

Dissect the skin from the maxilla as far as the ventral margin of the orbit and cut the nasal cartilages. Dissect the skin from the nasal and frontal regions, including the upper and lower lids, but leaving the third lid, *Membrana nictitans*, attached to the ball. Remove the skin from the rest of the head, dividing the *meatus auditorius* close to the head. The *parotid gland* will be removed with the ear, but the *submaxillary*, of a darker color, will remain with the head. Reflect the skin from the cervical muscles for about 2 cm. caudad of the *crista lambdoidalis*.

Dissect the origin of the *M. massetericus* from the *zygoma*, noting that its cephalic and caudal borders are strengthened by tendinous bands which must be cut. Push a nipper-blade between the eyeball and the cephalic root of the zygoma, and nip the latter as close as possible to the maxilla. Then nip the caudal root at the angle between the transverse and longitudinal parts of the zygoma, just laterad of the *Fossa glenoidalis;* remove the zygoma with the bone-scissors.

Grasp the lateral aspect of the eyeball with the forceps, and rotate it mesad so as to expose its attachments, by the muscles and *N. opticus*, to the bottom of the orbit; cut the attachments with scissors, leaving the *Mb. nictitans* connected with the ball. If the eyes are to be studied or preserved, mark them right and left by numbers or tags; the proper position is always indicated by the *Mb. nictitans*.

Slightly ventriduct the mandible and move it from side to side so as to indicate the position of the *Ath. temporomandibulare*. Often the capsule has been opened already in nipping the caudal root of the zygoma. If not, it is to be cut while on the stretch by inserting the arthrotome, and cutting until separation is complete on that side.

Dissect the *M. temporalis* from its cranial origin, and then from its insertion upon the *processus coronalis* of the mandible. Then bring the mandible to a right angle with the rest of the head; feel for the caudal border of the hard palate, and for the tips of the *processus pterygoidei;* at a point midway between them push a scissor-blade entad of the soft palate, and divide it; then divide the mucosa forming the dorsal wall of the *postnares*, and dissect it from the basis cranii to the atlas.

The mandibles are now attached to the rest of the head by some muscles, by the mucosa at the angles of the mouth which may now be divided, and by the slender piers of the *hyoid arch*. These last join the skull at the lateral side of the bullæ, where they are to be divided with the arthrotome; if it be desired to examine the mode of their attachment, they may be cut with the bone-scissors at a little distance from the attachment.

Turn the tip of the mandible still farther ventrad and caudad, and dissect off the muscular masses that are inserted between the bullæ; near the caudal ends of the mesal borders of the bullæ emerge several nerves, which should be divided with the scissors or a sharp scalpel at about 1 cm. from the skull. By continuing the removal of the muscles across the *Ath. atlo-occipitale* this is exposed. Put the membranes upon the stretch, and divide them with a sharp scalpel along the cephalic border of the atlas. This exposes the *myelon*, which is to be divided in the same way. The remaining ligaments and the cervical muscles may be cut with the arthrotome and the skull proper is then separated from the rest of the body. Place the skull in the *n. s. s.*, and wash the hands and the instruments which have been used.

EXPOSURE OF THE BRAIN.—The method here described is by successely removing bits of the skull with the nippers.

Caution.—In the later stages of the operation there is considerable risk of injuring the brain by the unintentional pressure of the nippers. In whatever way the bone is grasped, when force is applied, the tendency is to approximate the cutting edges as nearly as possible, and thus to bring their planes into right angles with the surface of the bone. This of course crowds the convexity of the ental blade against the brain, and may crush it seriously. It may occur either from the turning of the nippers in the hand, or more frequently from the escape of the skull from the grasp of the other hand. The accidents may usually be avoided by keeping the matter in mind, by having the right hand dry, and aiding the grasp of the more or less slippery skull by a small towel or bit of coarse muslin; this last is also desirable during some stages of the operation as a protection of the hand itself from abrasion.

In using the nippers another precaution is to be observed. If the bit of bone to be removed is attached only to bone it may be either cut or broken, or twisted off; but if it adheres to the *dura* or other soft parts, only *cutting* should be employed, and that done with care.

During the exposure of the brain the head should be frequently dipped into the *n. s. s.* If obliged to suspend the operation for more than an hour, wrap the head in a cloth wet with the *n.s. s.*, and set in a cool place.

Nip off the caudal root of the zygoma, including the *Fs. glenoidalis*. Insert a nipper-blade into the *meatus auditorius*, and remove the bulla in fragments. With the scissors cut away the membranes attached to the margin of the *Fm. magnum*. Nip off the occipital condyles, with the intervening area of the *basioccipital* for 2-3 mm.

* The meaning of this and some other unfamiliar terms may be learned from a paper (9) in "SCIENCE" for March 19 and 26. Most of the words employed are to be found in a Human Anatomy, or a dictionary, general or medical.

from the foramen. Insert a nipper-blade between the dura and the bone 5–6 mm. from the meson and in line with the mesal border of the cephalic part of the bulla, and nip out the basioccipital as far as the middle of the length of the bulla. At or near the angle left after the removal of the condyle and the basioccipital, the *N. hypoglossalis* enters the *Fm. condylare*, and passes cephalad to emerge on the ventral aspect of the skull by the *Fm. jugulare*. If the series of roots do not appear, carefully remove a little more bone until they do. If the nerve-roots are to be especially studied, endeavor to nip off the bone surrounding the *Fm. condylare*, so as to save the trunk. On emerging upon the ventral aspect of the skull, the *N. hypoglossalis* will be found to lie practically in the *Fm. jugulare*, and to be more or less intimately attached to the *NN. glossopharyngealis, vagus* and *accessorius*, which penetrate the bone by that foramen. In attempting to separate the *N. hyp.* great care must be used to avoid any traction upon the roots, which readily pull out of the medulla. Of the other three nerves, the *accessorius* is the most caudal, and the most readily distinguished, but at this stage it is as well to leave them together, simply endeavoring to remove the bone surrounding the foramen, and to save the trunks pretty long, at least upon one side. Upon the other, it will save time to cut the roots just entad of the skull, and the same may be done on one side with the remaining nerves, or with all upon both sides in case the brain is not to be employed for the study of the apparent nerve-origins.

The dorsal wall of the bulla is hard, but readily crumbles between the nippers. It may be removed in small pieces, so as to save the *NN. facialis* and *auditorius* which enter the *Fm. auditorium internum*, and the little *Lobulus appendicularis* of the cerebellum which is lodged in a slight fossa just dorsad of the foramen.

Since no nerves are transmitted by the mesal region of the basis cranii, it may be removed with comparative freedom, as far cephalad as the *pituitary fossa* where some care is needed to avoid injuring the *hypophysis*.

The skull may now be held more securely by the facial region, especially if a towel is employed. In removing the bone at each side of the meson, and just cephalad of the bullæ, great care is required to disengage the nerves which emerge by the *FF. ovale, rotundum*, and *sphenoidale*. These nerves, the *NN. oculomotorius, trochlearis*, and *abducens*, with the *ophthalmic, superior maxillary*, and *inferior maxillary* divisions of the *N. trigeminus*, penetrate the bone more or less obliquely, and are closely surrounded by dense connective tissue.

Just cephalad of this series of foramina is the *F. opticum*, and the *N. opticus* is particularly hard to disengage without tearing some of the delicate parts (*terma*, or *lamina terminalis*, etc.,) which are connected with the *chiasma*. Since the optic nerves are always easily recognized, it is usually better to cut them pretty short with the scissors, than to run the risk of rupturing the terma.

The entire maxilla is now to be removed by first nipping the interorbital region just cephalad of the fronto-maxillary suture, and then, with the bone-scissors, cutting toward this point from just caudad of the cephalic root of the zygoma. The scissors should be kept as far cephalad as possible, so that the *Bulbi olfactorii* may not be injured. This plan serves equally well for some dogs, but with the larger breeds, which have prominent *bulbi olf.* the interorbital region should be nipped at about the middle of the length of the nasal bones.

Remove the mesal walls of the orbit, and the turbinated bones, using care not to crush the very soft *Bulbi olf.* The *Nervi olf.* should be divided, a few at a time, with the scissors or the tip of the scalpel, and all pulling and twisting of the parts must be avoided.

During the remaining steps of the operation, the head must be held by the parietal regions, and with great care, so as to avoid pressure of the tips of the fingers upon the brain. The bone, also, must now be *cut* by the nippers rather than twisted or broken. Nip off the *supraoccipitale*, including the dura, as far as the *Crista lambdoidalis*. To remove the ventral part of the bony tentorium, introduce a nipper-blade between it and the hemisphere on either side, in such a way that the greater convexity is toward the hemisphere rather than the cerebellum; the cut is to be made at the level of the *Sutura squamosa;* the width of the tentorium at this point is about 8 mm., and the nipper-blade should not be introduced to a greater depth than that, for fear of injuring the *Lobi optici*. In closing the blades the head should be held very firmly so that no rotation may occur. The detached ventral piece of the tentorium may be extracted by the forceps, or by the nippers used as forceps, any adhesions being carefully separated with the tracer or scissors.

Hold the head with the ventral side down, support the caudal divisions of the brain with a disengaged finger, and with tracer and scissors separate the cephalic surface of the cerebellum from the tentorium. Then hold the head with its caudal end down, and complete the disengagement of the *Bulbi olf.* Hold the head over the 7 p. c. brine, with the ventral side down, and nip out, piecemeal, a triangular piece of the calvaria, nearly to the tentorium. The mesal adhesions of the dura may be divided with the scissors, but elsewhere the dura is to be left upon the hemispheres. As the hemispheres begin to fall, hold the head so that they are supported by the brine, and then snip all remaining adhesions until the entire brain is free and floats in the liquid.

REMOVAL OF THE DURA.—Saturate some cotton with the brine, and place it under the brain, so that about one-third of the organ projects above the surface. Avoid handling and lifting the brain; move it by shifting the cotton, or by grasping the dorsal portions of the dura. Remove the dorsal and lateral parts of the dura by grasping the free borders left by cutting along the dorsimeson, and cutting out piece by piece with the scissors. Then grasp the *falx* just dorso-caudad of the *Bulbi olf.*, at the straight transverse fissure—*F. cruciata;* introduce the scissors about 5 mm., and cut the *falx*. Gently draw the cephalic portion cephalo-ventrad between the *Bulbi olf.*, and remove it. Draw the caudal portion caudad, and carefully cut all its attachments.

Turn the brain upon its dorsal surface, and remove the ventral portions of the dura with great care and in small pieces. Especial pains are needed in connection with the hypophysis and the nerves, and all pulling must be avoided. On one side, at least, it is well to leave the dura still attached to the nerves and the great *Gasserian ganglion* upon the *N. trigeminus*, to be more completely removed at the time of the removal of the pia.

TRANSFER TO THE ALCOHOL.—Place a large spoon or watch-glass at the side of the brain, and pull the cotton which supports it, so as to roll it into the glass, resting upon its dorsum. Let the brain slide off into the alcohol so as to rest on the cotton therein, still with the ventral side up.

Set the bowl with the alcohol in a cool place, and change the position of the brain at intervals of five to ten hours during the first three days, by pulling the cotton in various directions. At the end of about three days, transfer the brain to 95 p. c. alcohol, where it may remain indefinitely. For a few days, however, it should rest upon cotton, and its position be occasionally changed.

WEIGHING THE BRAIN.—If this is to be done, handling the brain may be avoided as follows; Place the bowl of alcohol into which the brain is to be put, upon the scales, and pour in alcohol of the same strength until it balances an even number of grams, *e. g.*, 400, 410, or 420. While the brain is in the spoon or watch-glass, pour over it some of the same alcohol, and then let the latter drain off as much as possible, by tilting the glass,

and supporting the brain with the fingers or a bit of cotton. Then transfer to the bowl of alcohol as above directed, and the increase in weight will represent, with approximate accuracy, the weight of the brain.

REMOVAL OF THE PIA.—This is most easily accomplished at the time of the removal of the brain to the stronger alcohol. At any subsequent period the pia is apt to be more firmly adherent. If the brain has been allowed to dry at all during its removal from the skull, the pia comes off with great difficulty.

Instruments and materials.—Forceps; fine forceps; medium scissors; wetting-bottle of 15 p. c. glycerine; cotton thoroughly wet with water, and so moulded as to form a sort of shallow cup in which the brain may rest without danger of rolling off.

Place the brain upon the cotton, and wet it with the glycerine. Then let it rest upon its ventral side, and grasp it in the cotton, firmly yet gently. Grasp with the forceps the fold of *pia* which occupies any one of the fissures, especially at the point of forking or junction with another fissure, and pull along the line of the fissure. Usually the fold of pia will come out easily, and with it will be removed some of the pia covering the free surface of the gyri between it and the adjoining fissures. Proceed thus until the pia has been removed from the dorsal and lateral aspects of the hemispheres. Avoid pulling across the line of the fissures. The larger forceps are easier to work with, and less apt to puncture the brain; but the fine forceps are sometimes required for the removal of the pia from the bottom of a deep fissure. The caudal surface of the hemispheres may be reached by slightly ventriducting the cerebellum. The mesal pia can only be removed close to the margins of the hemispheres.

On one side, preferably that on which the *N. opticus* was cut shorter, raise the mass of nerves formed by the divisions of the *N. trigeminus* and *N. abducens*, by its lateral border, and cut with the scissors the *N. oculomotorius* which holds the mesial border close to the brain. This will permit the mass to be turned caudad so as to expose the course of the slender *N. trochlearis* which emerges from between the hemispheres and the cerebellum. It also permits the removal of the pia from the region just laterad of the hypophysis. Grasp the pia on the ventrimeson just caudad of the *Bulbi olf.*, and pull caudad so as to remove it as far as the chiasma, taking care not to tear the delicate *terma* just dorsad of the chiasma. Then remove the pia from the olfactory tracts.

In removing the pia from the medulla the position of the nerve roots should be constantly kept in mind, and the traction should be laterad and cephalad. One of the most difficult things is to preserve uninjured the series of roots of the *N. hypoglossalis*, for their connection with the pia seems to be closer than with the medulla. Sometimes it may be necessary to let the brain be wholly below the surface of water or alcohol so as to float the roots out, and render them more apparent.

As suggested on a previous page, it is often as well to leave the roots longer on one side than the other, but the choice may be determined mainly by the degree of success in the various operations which have been described.

If desired, later numbers of "SCIENCE" will contain directions for the general dissection of the brain. Meantime, it would be well for the student to make outline drawings of the brain he has prepared, especially of its base. Most of the principal features of this surface can be identified from the figure of the corresponding surface of the human brain to be found in any good Human Anatomy. The drawing should be enlarged two diameters, and the brain should be kept wet with the glycerine mixture, while it is out of the alcohol.

ATOMS AND MONADS, THEIR METAPHYSICAL DEVELOPMENT.

By DR. DIODATO BORRELLI.

(Translated from the Italian by the Marchioness Clara Lanza.)

In previous chapters of this work [1] it has been shown that the whole product of our psychological activity typifies a purely metaphysical world. It has likewise been seen, that the vast compound of forms by means of which exterior nature is represented to us, is not an extrinsic reality, but merely our own impressions, the result of slow and unconscious practice. A minute physio-psychological analysis leads us to this necessary conclusion. Colors are mere modifications, induced in certain groups of ganglion and cephalic cells by a stimulus which acts upon the organs of sight. Sounds are another form of cellular modification determined by a different kind of stimulus. Weight and resistance are phenomena of muscular sense. Form and size, synthetic relations, and therefore purely subjective phenomena. All the complex qualities by means of which physics are able to recognize different bodies, are nothing more than our own determinations. From this we may properly conclude that body and matter are not extrinsic realities, but a complication of modifications produced within us by exterior impulses.

Our world is therefore purely phenomenal, and not a reality. Herbart reasonably maintains that the first moment of research must necessarily be one of doubt, or scepticism, which is degraded or elevated in proportion as the uncertainty concerns things as they seem to us, or whether it relates to existence itself. Does the reality exist? This is the first question which presents itself to the philosopher. And if it does exist, what constitutes it and the consecutive research? "We cannot deny the reality," says Herbart, "because, to do so, is to remove all possibillity of the phenomenal world before mentioned. Sensations, representations and thoughts would be completely annulled."

This phenomenal world, resulting from the data of experience, is that which induces us to admit the existence of positivism. But these data do not constitute real existence, because they are not self-subsisting, but depend upon something else. That is to say, they exist in something else and by means of something else. *Actual existence* does not admit of either relation or dependence, it is based upon itself, and is, therefore, an absolute con-

[1] Borrelli. *Vita E Natura. Studii sui temi più importanti del Moderno Naturalismo.* Naples, 1880.

dition to the full comprehension of which we cannot attain, although we cannot fail to recognize it. The positive is, therefore, something to which this absolute existence attaches itself—it is in fact, a quality.

According to Spencer,[2] positiveness is nothing more than *persistence in the consciousness;* "unconditional persistence, such as the mental perception of space, or conditional, such as the intuition of a body we hold in the hand. That which establishes the persistence is really what we call positiveness, of which, (although we have demonstrated that the positive within our own consciousnsss is not objective) we, nevertheless, form an indefinite idea as being something which persists absolutely, in spite of all change of mode, form or appearance."

Spencer's definition, however, is in some respects open to criticism. First of all, if by consciousness, individual consciousness is to be understood, can anything persist which is merely an illusion without any definite existence? This can only happen under certain pathological conditionns of the mind. But there is still another point. Persistence in the consciousness is certainly a relation, because no thought can be produced without a relation, and even Spencer affirms this when he says; "We think relatively, every thought is based upon a relation."

However, according to Herbart, one of the principal conditions of absolute reality, is to be free from everything pertaining to dependence or relation. To avoid confusion, we must give more than one signification to the word positiveness. To begin with, we cannot ignore a *relative positiveness* which comprises all the conscious conditions of our being, and the famous sentence "*cogito, ergo sum,*" is in itself a peremptory demonstration of it. Sensations, representations, sentiments and all other familiar modifications are embodied in such positiveness. Whether they correspond to an objective effect or not: whether they are illusions of a diseased mind, or normal representations, is of little consequence. We know that they exist in our consciousness, and that is sufficient, inasmuch as they typify a real function.

We cannot say as much for objective or absolute positiveness. In regard to this, the experience of our senses teaches us nothing. We only know that it does not correspond to our individual sensations and that it differs from them essentially. In all our relations with the exterior world there is nevertheless a common and constant condition—an inexplicable something which acts upon our organs of sense and determnes the inward modifications. If, however, we rob Nature of our complex determinations, we leave nothing remaining but *stimulus* or *action*, which works upon us incessantly. The idea of objective or cosmic positiveness, originating from the data of experience, presents to us a conception of force or energy, combined with continual action. Absolute positiveness we can only understand as something corresponding to *permanent acitvity.*

The most ancient philosophers of Greece and India made extensive speculations as to what this natural force or activity might be, which operates in such manifold ways upon our senses and creates in us the most stupendous and varied phenomena. Indeed, human reason in Ionian, Pythagorean and Eleatic schools, seems to have been directed solely upon Nature under its various aspects.

According to Thales, water is the first general principle from which all other things are derived. In Anaximander of Miletus, a more condensed cosmological conception appears concerning the universe as being constructed out of *primitive matter*, which he called fundamental principle—an eternal, infinite, indefinite basis, from which everything originates and to which everything in the course of time, returns. This principle is not, as Aristotle appears to think, a compound which upon separation resolves itself later into particular forms. It seems easier to believe that the specification could only occur under some peculiar influence.[3]

We may well be astonished when we consider that six centuries ago a conception concerning the universe arose, which intimately resembles our modern cosmology. And our wonder is increased ten-fold when we see Anaximander produce from his fundamental principle the original antithesis of heat and cold by means of an inherent and eternal movement of the substance.[4]

According to Anaximanes, *Air* is the first general principle from which everything is produced by means of the double process of condensation and rarefaction. This theory should not appear strange to our modern mechanical school, according to which, particular forms of ethereal atoms are diffused throughout sidereal space, from which chemical atoms, and, consequently, all ulterior bodies are produced.

While the Ionian school deals principally with the sensible qualities of bodies, it aims more directly towards their inward substance. But we see in that of Pythagoras a new tendency, an increased abstraction. Paying but little attention to Nature, which is unknown to existence, he turns to consider order and quality, which are, indeed, realities. Numbers are the principle of all things; the Universe is only measure and harmony. Our quantitative relations, dimension, extension, form, distance, etc., are impossible without the aid of numbers, and therefore numbers are the first principle in all things, as they determine the order in which everything presents itself. Without stopping to discuss with Zeller as to whether the Pythagorean numbers are the substance or model of sensible things, we must particularly note that the idea of order and numbers is chiefly important in our modern conception of the Universe. If Nature really consists of but a single substance of various formations from whose elementary parts the specification of individual bodies is produced, it is natural to suppose that the true essence of all things by which they are determined, cannot be the indefinite cosmic principle, but a special disposition, which assumes its elements and the number in which they unite. *Numbers and disposition* form, as we shall see, the basis upon which modern chemistry rests.

With the Eleatic school which arose from a conception of *unity* and *immovability*, exaggerated to such an extent as to lead Zeno to a paradoxical denial of all motion, we come to Heraclitus, who, in direct opposition to the Eleatic school, speaks of perpetual flux and movement. The permanence of existence is merely an illusion. Positiveness may be compared to a river which disappears as it rises, and into whose waters, consequently, we can plunge but once. Heraclitus affirms that nothing remains equal to itself, that everything increases, diminishes, and finally dissolving, passes into other forms. Hence, from life to death, and from death to life again. The appearance and disappearance of these forms is, therefore, the perpetual vicissitude of the universe. In this stupendous doctrine we have the conception of future existence, which is nothing more than the harmonious blending of adverse tendencies. And in it we think to perceive the germs of the future theory of evolution. But it contains something else also. According to Heraclitus *fire* symbolizes the law of vicissitude. This is a profound doctrine which demonstrates to modern theories that no new formation or division of elementary bodies is possible without a corresponding modification in the inward action from which thermal phenomena are derived.

In the four roots of all things—fire, air, water and earth—there is first of all connection with the *sphere* and later a division. Upon this blending and separation depends the source and dissolution of all particular forms.

[2] Herbert Spencer. *First Principles.* 1871.

[3] Zeller, quoted by Fiorentino. *Manuale di Storia della Filosofia,* Naples, 1879.

[4] Schwegler. *Geschichte der philosophie.*

In Empedocles we find for the first time a confused perception of *attraction* and *resistance* in the sympathy and conflict which are the determining causes of the union and disunion of the elements.

Up to this time we have an irreconcilable antithesis between the Eleatic conception and that of Heraclitus. On one side, by exceeding the data of experience and elevating to the highest degree abstracts of material things, we find existence robbed of all determination and unchangeable. On the other, we have existence and non-existence bound together by means of the Future, from which springs the change and perpetual vicissitude of all things. But there is no fixed law for the Future of Heraclitus ; it is merely the result of experience, nothing more. Why, therefore, does existence change? Why are forms produced only to be again dissolved into something else? An attempted explanation was given, as we have seen by Empedocles; sympathy and resistance attract and repulse the four radicals of all things, and all forms are produced by the attraction which the repulsion afterward disunites and destroys. This is a profound conception, but yet somewhat obscure and undecided.

It was the *Atomical* school which took gigantic strides along this path, finally reaching those massive theories which even to-day we must look upon with admiration. Its founders were Lucippus and Democritus,but the latter is undoubtedly the most celebrated. We will go over the most important points in his doctrine, as they are related by Fiorentino.

"Existence is not a unity, but a combination and an infinite one, composed of many minute and invisible bodies which move about in space, unite and produce life, then separate, and cause death. They are capable of union and disunion, but never of change, and just as they are in the beginning, so they will always remain.

"We can distinguish in atoms form, order and position which are the primitive qualities which serve to produce others. All atoms are not equal; all have a downward tendency, but the lighter rise above the heavier producing a rotatory motion which extends and forms bodies."

Atoms, moreover, are impenetrable, and as units cannot be divided. They are consequently distinct one from the other, well defined and unconfused. This necessitates the interposition of something which tends to keep them separate. It can be nothing more than the *opposite* of the mass, vacuum, which causes interceding intervals between the atoms and holds them apart. Without vacuum, no motion could be possible, as the mass can receive nothing more in itself, or be augmented in any way, because this can only be obtained by the introduction of new atoms in the vacuum. We have, therefore, two contending agencies—existence (atoms) and non-existence (space), which go to represent objective positiveness. The final and most important of atomic theories bears the stamp of unconscious and unintelligible *natural necessity*. Motion can be determined by no cause. It is as eternal as the atom itself and is a part of its nature. It is easy to understand therefore, however far it may depart from the truth, the opinion of those followers of Democritus who attribute the origin of the world to chance.

By the atomical theory we have reconciled therefore, the unchangeableness of existence with the perpetual transformation of things; transformations which have nothing to do with the substance, but which spring from special arrangements of the atoms determined by motion. We shall shortly see how the fundamental doctrines of the atomical school have been reproduced in our modern mechanical one after a lapse of four centuries.

The Grecian mind was not satisfied with the mechanical explanation of future existence. We consequently see brought to light for the first time by Anaxagoras, an immaterial principle *Nous*—an intelligence apart from all matter, maker of the world. In short, an agent with a definite purpose. This intelligence, although motionless itself, is the cause of movement, and the formation of the *panspermia* or *omeomeria*, as Aristotle calls it, is the result of its action. This is the systematic and beautiful origin of the world.[6]

This intelligence, however, is not a personal god, because it possesses no action in itself and its operation develops solely in the motion and order of matter. Plato and Aristotle are quite right when they blame Anaxagoras for holding to the mechanical doctrine while having an instinctive perception of the final cause.

The *Nous* of Anaxagoras, as Schwegler has observed, closes the period of anti-Socratic realism, that is to say the conception of natural positiveness as represented by ancient Grecian philosophy. Anaxagoras embraced the principles belonging to the preceding schools which he attempted to reconcile, but he made apparent for the first time an *ideal* principle, which being accepted by Socrates, afterwards expressed the new and adverse current of Grecian thought.

Atomism reappeared with Epicurus, not presenting, however, any novel determination, except that the atoms did not all descend in a direct line giving rise to a whirling motion, as Democritus affirms, but proceeded each separately in its own way guided by a kind of free will.

Throughout the long period of ideal speculation which succeeded ancient Grecian philosophy, investigation in regard to cosmic positiveness being looked upon as a matter of secondary importance or else neglected altogether, naturally made no progress whatever Thus we come to the Sixteenth century, during which a single voice in England was raised to deplore the false road upon which human thought had traveled for so long, agitated and confused by empty and useless discussions. Logic seemed to aim towards the "strengthening of error rather than the search for truth." "And this," said Bacon, "can proceed from nothing but the fact that scientific research is alienated from its true source—nature and experience—to which it must return if anything is to be achieved." Although many errors crept into the facts accumulated by Bacon among his perceptions of great truths, he, nevertheless, rendered an immense service to science by recalling it to experiment and to the inductive method. About the same time, a great Italian, Galileo, not only proclaimed the system, but applied it, gathering much more fruit from his enterprise than did the English philosopher.

This was one of the grandest moments known to the human mind. In this period, which we call the Renaissance, while man, no longer satisfied with the narrow boundaries of the old world, discovered new paths while in search of other lands, human conscience oppressed by centuries of overbearing slavery advanced towards reformation. Then speculation, shattering its scholastic fetters, opened a new field for research, and resolved to cultivate it by fresh methods. Later we shall see the abundant fruit which grew, not so much from the field of abstract speculation as from that of natural investigation.

René des Cartes here broke in with past traditions, endeavored to make the research over again from the beginning, and commenced to exclude all supposition and to entertain doubts about everything. But the new structure of facts which he built upon Thought was precisely the contrary of his method. Positiveness according to des Cartes is represented by three substances—God, Mind and Matter. Thought is the attribute and essence of mind; extension is the attribute of matter. Here, then, is cosmic positiveness reduced to nothing more than *expanse*, while in our opinion it is the very opposite. Expanse is merely a relation, and it annuls the absolute condition of existence reducing it to a simple *rapport*.

[6] The panspermic theory affirms that the germs or elements of all things exist in the earth, and only require a particular combination of circumstances to bring them forth.—TRANSLATOR.

In the monadology of Leibnitz, we find a reversion to atomism under an ideal form. He considers the substance of the universe as an active force, represented by monads. These, after the manner of atoms, are a distinct unity, unchangeable and indestructible. Contrary, however, to atoms, which do not present any qualifying diversity in themselves, monads are distinguishable one from the other, each one personating, as it were, a distinct form. Moreover, atoms being capable of expansion, can be regarded as separable, but monads cannot, because they are metaphysical conditions. And inasmuch as metaphysical conditions, no matter how they unite, can never go beyond a certain limit, Leibnitz denies the objective reality of space, and looks upon it as a kind of co-existence.

But the most important part of his doctrine is the conception he places upon the action of monads. Each one has its peculiar representation apart from the other monads and consequently, the universe. All the ulterior developments of the latter are therein portrayed, so that in monads we may read the future. Such representative power is not the same in all of them, however. Some, monads of the lowest degree, have a confused representation which may be compared to vertigo or dreamless sleep; a condition in which representations are not wanting, but being neutralized cannot attain consciousness. These lower orders of monads represent the first link belonging to the chain of existence, which is called inorganic nature, and the bodies resulting from them may be likened to a fish pond whose elements are alive while it is not.

Occupying a higher grade, in the vegetable kingdom, are monads in which representation acts as a formative vital force, but always totally unconscious. Higher still, in the animal world, monad life rises to sensations and memory, and finally to reason and reflex action. However, let us repeat, in order that it may be well understood, that the representative contents of the various orders of monads do not differ, because each one, like God, reflects the entire universe *(parvo in suo genere deus)*. The difference lies solely in the clearness and perfection of the representations.

We will not linger here, however, that we may slowly follow the ideas of Leibnitz in regard to the relations existing between God and monads, or between them and the soul by means of pre-established harmony. We will merely observe that if we remove from monadology all the purely imaginary elements with which it overflows, there still remains something both novel and important which is not to be met with in old atomical theories. This novel determination consists in a peculiar active force which each monad possesses *internally*. It is a prior intuition of *pampsichism* which being enriched moreover by positive facts, can lead the way perhaps, to the greatest reconciliation of which the human mind is capable.

We find another reversion to atomism in the metaphysics of John Frederick Herbart. We have already seen his conception of absolute positiveness. However, experience receives many suggestions from the phenomenal world, which is composed of manifold appearances. And as every appearance insinuates a determined Reality, the latter must be considered as a compound of several single entities or monads, each one posessing different qualities. The individual groups of these monads are those which, working upon our senses, there produce the representation of definite objects. We find a vast difference between Herbart's conception and that of Hegel; while the former considers Nature as a plurality, the latter conceives it to be a unity. To one, absolute positiveness is the Ideal, while for the other, on the contrary, it is Reality.

But how can we reconcile the absolute condition of the Real, the peculiar conservation of monads with the phenomenon of mutation. Herbart has recourse to *accidental perceptions* and *intelligible space*. By accidental perceptions, we mean the manifold relations which can proceed from a single conception, according as it may be compared with others, but, nevertheless, remaining always unchanged. Thus, for example, a straight line can be considered as a radius or as a tangent without changing its position, just as a sound can be harmonious or discordant, according to the relation it bears towards other tones. In the same way, in the grouping of various qualities of monads, while on one side there is no change, on the other there is a very perceptible one. By means of *intelligible space* we may consider existence either as a complex form or as an individuality.

This theory, which in some ways closely resembles the old atomic dogma, is far removed from it, inasmuch as the monad or atom, according to Herbart, does not possess an impenetrable character.

Looked at from a mathematical point of view, several monads may coincide perfectly one with the other. Between the monad of Leibnitz and that of Herbart, there is also a noteworthy difference, because the former considers the *internal condition* as original and individual; while with the latter it is wanting, if we consider a single monad, but develops with the reciprocal relations between the monads.

We will finish with Herbart, our brief explanation of atomism revealed upon a field of pure metaphysical speculation. On the other hand, a new doctrine arises, an experimental one, from which we shall see produced an atomic theory, which is not the work of more or less arbitrary deductions, but the slow result and synthesis of a multitude of positive facts.

ASTRONOMY.

SPECTRUM OF "LALANDE 13412."

We are indebted to Prof. Pickering for the following note upon some observations recently made at Harvard College Observatory:

"The star *Lalande* 13412 has a very curious spectrum. It belongs to the same class as *Oeltzen* 17681 and the three stars in *Cygnus* having bright lines. Besides the yellow and blue bands, it has a marked line in the green, which is faint, if not wanting, in the other stars. It is also about a magnitude brighter than either of them, so that it is the only object of the kind within reach of small telescopes. Professor Young found *Oeltzen* 17681 difficult with 9-inches aperture, while I discovered this object with 4-inches aperture. The position for 1880 is:

R. A. 6^h. 49.3^m.
Dec. —$23°$ $47.'$

or about 15′ north of *o Canis Majoris*. In winter this star is conveniently observed when all the other stars of this class are below the horizon.

The same evening I found that the spectrum of a^2 *Puppis* is banded. As the declination of this star is —44½°, this is probably the most southern object ever usefully observed here. Its altitude at the time of observation was only about 2°!"

The Transit of Venus Commission established by the French Academy of Sciences, has resumed its labors under the presidency of M. Dumas. A credit has been given by the Government for constructing new refractors. Not less than twelve are now building, to be used on the several stations which have been already selected, and will be ready by the end of the year. The heads of the scientific missions will soon be appointed, as well as their staff. The greater number of instruments built for the 1874 transit has been disposed of to several public institutions.—*Nature*. W. C. W.

WASHINGTON, D. C., April 6, 1881.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE:"

It is with mingled pleasure and profit that I have read the very suggestive paper on cerebral nomenclature contributed to your latest issues by Professor Wilder[1]. Some of the suggestions which he has made have been latent in my own mind for years, but I have lacked the courage to bring them before my colleagues. Now that he has broken ground, those who prefer a rational nomenclature to one which like the *present* reigning one, is based upon erroneous principles, or rather on no principles at all, will be rejoiced at the precedent thus set for innovations. As Professor Wilder has invited criticism, I take the opportunity of offering the following remarks upon the leading points of his papers, in so far as they refer to the brain alone.

1. The principles announced are such as zootomists and anatomists generally will agree with, to the fullest extent. He who has himself been compelled to labor under the curse of the old system, the "beneath," "below," "under," "in front of," "inside," "external," "between," etc., of anatomy, as taught at our graduating mills, will look upon the simple "ventral" "dorsal," "lateral," "mesal," "cephalic," (or "nasal" or "proximal") and "caudal" ("distal") as so many boons. I have no hesitation in saying that the labor of the anatomical student will be diminished fully one-half when this nomenclature shall have been definitely adopted. I suppose, however, that the present generation of teachers—I am speaking of our medical schools, not of our universities—will have to become extinct before even the attempt can be made. In Germany the older system has gone out of use almost entirely, and not the least charm about the works of Henle, Schwalbe, Forel, and Gudden, is the fact that these authors have more or less done away with the ambiguous terms once rampant.

2. At present two terms are used convertibly; these are *crus* and *pedunculus*. The chief parts to which these terms are given are the *crus cerebri* (*pedunculus cerebri*) and the *pedunculi cerebelli* (*crura cerebelli*). If anatomists would agree to use the term *crus* only for the cerebral tract, and *pedunculus* for the cerebellar, it would save us the necessity of adding another word. *Crus* would mean what *crus* or *pedunculus cerebri* now designates, *pedunculus* a cerebellar tract. The modifications suggested by Professor Wilder of *præpedunculus*, etc., are excellent. The word *pedunculus* has been applied to a number of other structures, but, I think, inappropriately; thus, *pedunculus conarii*, *pedunculus hypophyseos pedunculus flocculi*, *pedunculus nuclei lenticularis*, *pedunculus substantiæ nigræ*, from all of which it should be removed, as there are other terms in use for these structures, or they are non-descriptive, as the latter two given.

3. In proceeding to comment on some of the terms proposed by Professor Wilder, I wish it to be distinctly understood that I do so merely tentatively and to promote discussion; in so doing I feel certain that I am carrying out that writer's wish. It is but just to state that the majority of the terms cannot be discussed, they are perfection and simplicity combined.

AMYGDALA (*Cerebelli*), W.—Since there is a *nucleus amygdalæ* in the temporal lobe of the cerebrum of man, simians and carnivores, which should be called *amygdala* briefly, just as the *nucleus lenticularis* and *n. caudatus* are termed *lenticularis* and *caudatus* and as the synonym *tonsilla cerebelli*[2] is at our disposal for the similarly named lobule of the cerebellum, I suggest replacing this term as applied to the cerebellum by *tonsilla*.

AREA INTERCRURALIS, W.—I have this term in a manuscript of mine, and am glad to find such a coincidence in baptism, according the priority, of course, to the first publication. I bound this area cephalad by the caudal border of the chiasm, caudad by the cephalic border of the Pons, laterad by the crura, and distinguish the deeper part as a *fossa intercruralis* (*substantia perforata post.*) The gray mass here located is the ventral face of Gudden's[3, 4] interpeduncular ganglion, which I propose, in order to secure nomenclatural uniformity, to term (*Ganglion*) *intercrurale*.

AREA POSTPONTILIS, W.—The objection can be made that this area is not homologous in different animals. A large part of the true Pons in man includes the portion homologous with a part of the *Area postpontilis* of the cat. The roots of the abducens nerve (6th pair) seem to me to constitute a more fixed boundary.

CAUDA STRIATI, W.—I have identified this structure in the cat; it does not make as fine a sweep as in man, but is distinct at the roof of the inferior horn and loses itself as has long been known[5] in the case of the human brain near the *Nucleus amygdalæ*. Professor Wilder's term is the only admissable one, both as being descriptive and on grounds of priority. *Cingulum* is otherwise appropriated.

CONARIUM, W.—Would not the retaining of this name deprive us of that convenient antithesis which can be established between *epiphysis diencephali* and *hypophysis diencephali?*

DENTATUM, W.—Some term should be devised which will at the same time express the fact that this gray mass is a nucleus of the cerebellum and differentiate it from the *nucleus fastigii* (*fastigialis*). *Dentatum* is not appropriate, in my judgment, because in those animals in which it is dentated, there are other dentated nuclei, and also because it is not dentated at all in the rodentia, the carnivora, and ungulata.

EPENCEPHALON.—Are there any reasons why a seperate segment of this name should be made? Some authors limit the term to the cerebellum, which latter is only a dorsal hypertrophy, not an entire segment. The difficulties which Prof. Wilder mentions could be obviated by abandoning the term altogether.

LEMNISCI W.—Can be identified in cat on transverse section; they are not distinct on the surface, nor indeed there well marked in any animal.

LOCUS NIGER.—This ganglion is not black in any animal except man; for this reason I have employed the non-committal designation of *Ganglion Soemmeringii*.[6] It is interposed between *pes* and *tegmentum* like a *diaphragma*.

MONTICULUS.—Modern authors[2], to my knowledge, employ this term only for the highest point of the dorsal cerebellar vermis.

NUCLEUS LENTICULARIS. Might be briefly termed *lenticularis*.

PONTIBRACHIUM, W.—Is identical with the *medipedunculus* of the same author. I have thought that analogous names might be adopted for the other *pedunculi*, thus *Restibrachium*, etc.

STRIATUM. W.—Why not *caudatus*? Both *lenticularis* and *caudatus* are parts of the old *corpus striatum*.

VENTRIPYRAMIS, W.—Since the "posterior pyramids" of descriptive anatomy are no longer known as pyramids, and the more generally used term of *Clavæ* has been employed to designate their intumescence, the prefix *ventri* may not be necessary.

4. Independently of the question of nomenclature, I should like to ask upon what grounds it is stated that *cerebrum* consists of the *prosencephalon* less the *striata*. The tissue of the cortex cerebri and of the two divisions of the *corpus striatum* are even in man continuous, and it would be impossible to peel out the lenticular nucleus from the white substance of the hemispheres. Indeed, embryologically the cortical gray and that of the cerebral ganglia are originally subendymal, and in tracing the development of the brain, as we proceed from reptiles to

man, we find that successively the *caudatus*, the *lenticularis* and the *claustrum* become differentiated from a common gray mass continuous with the cortex at the base of the cerebrum.

I would add in regard to the term CORTEX that the Optic lobes[3, 6] and the Rhinencephalon[5] exhibit the cortical structure as the cerebrum and the cerebellum.

The following terms not included in Professor Wilder's series, are submitted, and for them I invite the severest criticism. Some of them are established by others.

CAPPA (*cinerea*[1])—The gray cap covering the *Optici*, well developed in most mammalia, rudimentary in man.

ECTOTHALAMUS*.—The outer gray thalamic zone.

ENTOTHALAMUS*.—The inner gray thalamic zone.

INTERCRURALE*, (*Ganglion*).—*Ganglion Interpedunculare*[3, 4].

SIGMA*.—The *S* shaped involution of the nerve-cell layer of the cortex which constitutes the basis of the *Hypocampa*.

NUCLEUS TRAPEZII*. — The superior olive. The development of this body seems to bear an inverse relation to that of the true olive. In man the olive proper is highly developed, in the cat poorly—in the latter the nucleus of the trapezium is well marked and folded; in man it is ill-marked.

OBLONGATA*.—The post-pontinal area of man; the *medulla oblongata*.

STRIÆ*.—The *striæ medullares albæ* of the fourth ventricle.

VELUM CEREBELLI*.—The valve of Vieussens; this is the true embryonic starting point of the Cerebellum. The *velum medullare anterius*.

VELUM OBLONGATÆ*.—The *velum medullare posterius*. It arises from the internal division of the *post pedunculus* in its oblongata portion, and covers the posterior part of the fourth ventricle.

VELUM FLOCCULI*.—The *velum medullare inferius*.

GRACILIS* (*Funiculus*).—*Funiculus gracilis*, continuation of corresponding column in cord; part of the posterior pyramids.

CUNEATUS* (*Funiculus*).

TUBERIS* (*Funiculus*).—Funiculus of Rolando; the columnar field containing the Tuberculum of Rolando. There is a *lobulus tuberis*, which is otherwise provided for.

NODI*.— Two symmetrical eminences, situated each in the shallow depression bounded by the *opticus, thalamus* and *habena*, probably corresponding to the *ganglion habenæ (Gangl. habenulæ*[5]*)*. There is a notable large opening cephalad of these eminences, which resembles the opening under the *tænia* containing the vein which gives the latter its bluish color. I can find no notice of this opening anywhere. The eminences are represented obscurely in Fig. 70 of Henle[2].

DECUSSATIO FONTINALIS.**—Fontanen artige Haubenkrenzung.[5]

In conclusion, I would urge the adoption of some brief arbitrary affix or prefix in place of the words commissure and ganglion. He who limits himself to a study of surface contours will not appreciate the absence of such abbreviations as much as he who is compelled to wade through the labyrinth of the internal cerebral structure.

Gris for ganglion would perhaps do; thus *Grishabena, Gristegmentum, Grisfastigium* for *Ganglion habenæ, Ganglion* and *Nucleus tegmenti, Nucleus fastigii*. The term *nucleus* is a very unfortunate one as it has another and very different meaning, which in my experience as a teacher of cerebral anatomy, has led to confusion in the mind of every beginner. Professor Wilder, who appears to be as much at home in etymology as in cerebral anatomy, will solve these problems no doubt better than I could pretend to.

* Terms proposed by myself, not to be found in previous publications.

** A single affix or prefix might be devised in place of *decussatio*, or *fontidecussatio, pinidecussatio, pyridecussatio?*

HOW DOES GRAVITY CAUSE MOTION?

To the Editor of "SCIENCE:"

The interesting article by Mr. E. L. Larkin in "SCIENCE" for March 26, on the Interrelations of Gravity, Heat, Motion, etc., induces me to offer you some thoughts on the subject, with the hope that I may throw light upon it from another point of view. There is one widely accepted doctrine of modern physics which I confess I could never understand, that of Potential Energy. It may serve as a convenient explanation of the mysteries of falling force to say that energy may be at one time motion, and at another time the possibility of becoming motion. The rule explains the problem, but what explains the rule? Can motion become anything else than motion? Can it now convert itself into Rest, into Gravity, into Potentiality, or into anything else than simply motion? Is it not, like force and matter, an unvarying infinitude of the universe?

Motion means simply the translation of substance through space, and it possesses a fixed energy dependent upon the weight of the substance and the speed of the translation. If the portion of substance moved be a minute portion of matter, either forming an elementary constituent of a solid mass, or a separate molecule of a gas, we call its motion heat; and the result of its impact with exterior particles, temperature. If it be a mass of such particles its translation should be particularized as mass motion. In addition to these modes of motion, Electricity and Magnetism must also be considered as more special modes of motion, unless we admit the possibility of motion becoming something else, and this something else again becoming motion.

Can we admit this? What does terrestrial gravity teach us? If gravity is convertible into motion, then we have reason to conclude that the gravity should disappear as the motion increases. The law of gravitation asserts that the action of the earth and of a falling body are necessarily reciprocal. The earth must fall towards the body with the same energy that the body displays in falling towards the earth. The body, then, can not derive its energy of fall from the earth, unless we claim that the earth derives its energy of fall from the body. Such a cross-lending of force is inadmissable. The energy displayed by the body must come from itself, not from the earth. It is not a transformation of the earth's gravity into motion. Is it a transformation of its own? This we cannot admit, since the body loses no gravity. It cannot well give and keep at the same time. The body falls 16 feet in the first second, and ends with a velocity of 32 feet per second. This 32 feet per second is a positive momentum, and must continue until over-

come by counter force. But if a portion of the gravity of the body has become transformed into this motion there will certainly be less to tr nsform during the next second. Yet in the next second the body adds to its 32 feet per second 16 feet more derived from gravity, and thus falls 48 feet, ending with a velocity of 64 ieet per second. In the third second it adds 16 feet to this 64, and falls 80 feet. And so on continuously, so far as observation has gone.

This certainly does not look like a transformation of gravity into motion, since the gravity appears to continue undiminished. And as to potential force, or possibility of motion, being converted into motion, I shall not attempt to combat it, for it is a sorry task to wrestle with an antagonist who changes into a mist when you attempt to grasp him. Gravity is something definite, whatever that something is, but this will-of-the-wisp of potentiality certainly lacks the bones of a solid body.

But if not gravity or potentiality what is it that becomes motion in the ball that falls towards the earth, and in the earth that falls towards the ball? This may seem a difficult question, and yet it admits of but one answer. Nothing becomes motion. Nothing can become motion. Motion is motion and cannot possibly be or become anything else. The motion which appears in the falling body was not created for the purpose. It existed in the falling body in some other form, and has been simply transformed, not created. Every mass of matter has its internal motions; its electrical, magnetic and chemical energies, which are more or less engaged in preserving the integrity of its molecules or of its mass; and its heat energy, which is engaged in a constant effort to overcome the integrity of its mass. The particles of the mass dart backward and forward continually. They would dart in one direction only were they not restrained by each other's resisting energies, and by external resistance. Consequently, any external energy which aids their vigor of movement in one direction and resists it in the opposite must give them a combined excess of vigor in that direction. They must all move more vigorously in that direction than in the opposite; that is, the mass must move as a whole in that direction. And this movement once gained is positive until overcome by exterior resistance. It is a definite energy which cannot be lost unless it be given to some other substance.

Such is the true principle at work in falling motion. Terrestrial gravity is the external energy which aids the vigor of the heat motion of particles in one direction and resists it in the other. This force is increasing. Although a mass be not fal'ing to the earth its particles are incessantly falling. The supporting body resists their fall and their excess energy in this direction expends itself upon this body. But if the support be removed there is no longer any resistance to their fall. The particles strike further downward than they return, since gravity aids their down stroke and retards their upstroke. Thus at each vibrarion of the particles the mass slightly descends. These slight descents continue. They are the energy derived from the pull of gravitative attraction. But each slight descent produces a fixed vigor of downward motion of the mass as a whole, and this vigor of motion is increased by constant new increments, so that the falling speed of the body rapidly increases.

This is the true meaning of potential energy—a change in the direction of motions already existing. No motion is created, or borrowed from any other condition of nature. The body gains force in one direction under the pull of gravity, but it is the force of a motive vigor which it already possessed, and which, instead of exerting itself equally in all directions, now exerts part of its energy specially in one direction. And this change in the direction of its energies is balanced by an equal opposite change in the direction of the earth's energies. The body does not possess the possibility of always falling, but it possesses the reality of always falling. Its particles constantly fall. But when it is supported their falls cannot accumulate. Each single fall is too slight to be observed, and the effect of each fall is overcome by resistance before another can be added to it. But these persistant falls produce a constant pressure upon the resisting substance, and constitute the weight of the body. It is on removal of the support that these rapidly repeated effects can be continuously added to each other, and become a visible descent. But the distance of the fall of the particles during each vibration is the same whether the body be supported or rapidly descending. It is only the preservation and accumulation of the positive mass motion given to the body by each slight fall, which causes the rapid increase in falling speed. These accumulating motions form an energy of motion separate from that of the fall, and which would keep the mass in motion at a fixed rate of speed were the force of gravity to suddenly vanish.

I would like to say a word here in reference to the presumed heated condition of the nebular mass from which it is claimed that the solar system originated. There is another reason than that advanced by Mr. Larkin, which renders it very improbable that the nebula was greatly heated. It is one thing to contain heat, another thing to be in what we call a heated state, that is, in a state of high temperature. For temperature and absolute heat are very different things. A mass of water at 32° contains far more heat than a mass of ice at the same temperature. And so a mass of water gas at 212° contains far more heat than an equal mass of water at that temperature. This rule probably holds good in all cases; namely, that as density diminishes the heat capacity increases, so that a very rare gas may contain a vastly greater quantity of heat than a solid at the same temperature. We see this exemplified in the matter of space. Heat has been pouring into it from the contracting spheres for an enormous period, yet its capacity for heat is so excessive that this outflowing heat has probably had very little effect in raising its temperature.

Such a consideration applies directly to the original nebula of the solar system. It was a very rare gas, and therefore had great capacity for heat. Its latent heat may have been great, and its effective temperature low. It was only after it began to rapidly lose heat that its temperature rose. For the contraction of the nebular mass must have, by condensing its substance, lessened its capacity for heat. If this change in condition took place more rapidly than radiation could balance it there must have been a steady increase in temperature, instead of a decrease as usually assumed. For all that we know to the contrary this phase of the process may not yet be completed. Contraction of the solar mass may yet be increasing its sensible heat, by lowering its capacity for heat, or its power of containing latent heat, more rapidly than this is balanced by radiation. In such a not impossible condition of affairs the sun would be yet rising instead of lowering in temperature, losing heat while increasing its apparent or sensible heat, and its process of actual cooling be not yet begun.

2223 Spring Garden St. Philadelphia. CHARLES MORRIS.

A CAUSE OF DETERIORATION IN CLOTH.—Goods dyed rust, buff, or chamois shades with salts of iron occasionally undergo a slow combustion. The ferric oxide is alternately reduced by the organic matter of the tissue and re-oxidized by the oxygen of the air.

AT a Berlin feather-dyeing establishment an ostrich feather dyed in shades with methyl-violet was layed upon a paper upon which some ammonia had been poured but had dried up again. After a time the feather became partially green, the green passing gradually into violet, and producing an extraordinary effect. This reaction is being utilized in feather-dyeing, and will probably be applied in the manufacture of artificial flowers.—M. BALLAND.

NOTES.

PERIODIC MOVEMENTS OF THE GROUND.—P. Plantamour gives an account of his observations on the movements of the ground from October 1, 1879, to September 30, 1880. The most remarkable feature is the sinking manifested on the eastern side from the end of November, 1879, to the end of January, 1880, which is much greater than might be expected from the absolute cold of the month of December, only —15°. A rise of temperature is always accompanied with an elevation of the ground level, and a fall of the thermometer is marked by a subsidence.

ON M'BOUNDON, THE ORDEAL POISON OF THE NATIVES OF THE GABOON; NEW PHYSIOLOGICAL, CHEMICAL, HISTO-CHEMICAL AND TOXICOLOGICAL RESEARCHES.—The poison employed contains exclusively one base, strychnine. E. Heckel and F. Schlagdenhauffen propose to examine whether the distinction between the tetanising and the paralysing species of the strychnos family may not depend simply on the proportion of the base which they contain.

ELECTRIC PHENOMENA OF TOURMALINE AND OF HEMIHEDRAL CRYSTALS WITH INCLINED SURFACES.—The hypothesis which J. and P. Curie put forward is that there exists a constant difference of tension between the opposite surfaces of two successive layers. Tourmaline being a compound body the different parts of a crystalline molecule may be formed of different substances, which would explain the difference of tension of the opposite extremities of two molecules.

VIOLET ILLUMINATION OF THE RETINA UNDER THE INFLUENCE OF LUMINOUS OSCILLATIONS.—A. Charpentier, fixing his eyes immovably on a sky illuminated by a uniform white light, and moving two fingers of his right hand rapidly and alternately backwards and forwards before them, saw, after a minute, a remarkable change in the uniform aspect of the heavens. There appeared on a white ground a mosaic composed of rather deep violet-purple hexagons, separated from each other by white lines, and forming a very regular design. The oscillations of the fingers should be from 300 to 400 per minute. He thinks that these hexagons are due to the cones in the fovea and in the yellow spot, and that the white lines are due to their intervals.

A GLYCOSIDE EXTRACTED FROM COMMON IVY.—The glycoside in question, $C_{64}H_{64}O_{22}$, is resolvable into a non-fermentible sugar, which reduces Fehling's liquid, and a neutral body, tasteless, inodorous, dextro-rotary, and agreeing with the formula $C_{52}H_{44}O_{12}$.—L. VERNET.

RADIOPHONY.—Radiophonic effects are thermic, not luminous, and are produced by gases alternately heated and cooled, and not by solids or liquids.—E. MERCADIER.

PERMANENCE OF HYDROCYANIC ACID FOR A MONTH IN THE BODIES OF ANIMALS POISONED WITH THE PURE ACID.—Hydrocyanic acid, if administered in a sufficient quantity to animals, preserves them perfectly for a month. It remains in the tissues, and especially in those of the stomach for the same time. It appears to combine intimately with the animal tissues. In the Carnivora it is more difficult to extract it by distillation than in the Herbivora. C. BRAME.

INFERIOR ORGANISMS PRESENT IN THE AIR.—The microscopic beings in the air are very unequally distributed. The germs of beer-yeast are not everywhere present. Bacteria are much less common than the moulds, such as *Penicillium glaucum*, *Mucor stolonifer*, etc.—E. C. HANSEN.

CHEMICAL CONSTITUTION OF ALBUMEN.—The transformation of albumen into peptones is produced by a hydratation, which in each phase takes place at a fixed part of the molecule. The regressive formation of albumen from its peptones is produced by a similar de-hydration. When the molecule loses calcium and phosphoric acid the carboxylic groups appear, and give an acid reaction to the groups thus obtained. In certain phases the molecule may lose a portion of sulphur without being destroyed or changing its properties.—DR. A. DANILEWSKY.

NEW RESEARCHES ON THE ALBUMENS OF MILK.—The albumen of milk is a mixture of stroma-albumen, with small quantities of orro-proteine and the synto-protalbes. The lacto-proteine of Millon and Commaille is a mixture of soluble synto-protalbes, of snytogenes, and of peptones, which alone are precipitated by mercuric chloride. The same mixture with small quantities of peptones represents the galactine of Morin.—DR. DANILEWSKY AND P. RADENHAUSEN.

DEVELOPMENT OF THE CADAVERIC ALKALIES (PTOMAINES).—MM. Brouardel and Boutmy have verified the presence of these poisons in the viscera of persons who had died either from the action of poisons or otherwise. The organs of an individual asphyxiated by carbonic oxide were analysed some hours after death, and found free from poison. On being re-examined eight days afterwards they contained a solid organic base, presenting the general characters of the alkaloids and proving fatal in small doses to frogs and guinea-pigs. The ptomaines are produced in the dead bodies of men and animals, and vary in their nature under circumstances not yet ascertained. They are poisonous in the majority of cases.

REPORT PRESENTED BY M. TROOST ON BEHALF OF THE COMMITTEE OF THE CHEMICAL ARTS ON THE MALLEABLE NICKEL OF MM. GASPARD AND BELLE.—The metal is first brought to a state of complete fusion, its surface is freed from all traces of scoriæ, a small quantity of metallic zinc or magnesium is introduced, the whole is stirred up and run. The metal thus added seems to lay hold of all traces of foreign matter derived from the sides of the crucible. Such nickel is ductile and malleable at all temperatures below its point of fusion, and can be welded either with itself or with iron or steel. Plates and wires of iron or steel can thus be coated with nickel.

SPECIFIC MAGNETISM OF OZONE.—Ozone being more magnetic than oxygen it is easy to see that the relation of the specific magnetism of ozone to that of oxygen is notably greater than the supposed relation of their densities. The specific magnetism of ozone is then greater than what would correspond to the quantity of oxygen which it contains.—H. BECQUEREL.

DETECTION OF ERGOT IN FLOUR.—The suspected sample is treated with cold ether or boiling alcohol to dissolve the greater part of the coloring-matters of the flour. The residue is then extracted with ether, mixed with a small quantity of sulphuric acid, and the extract is examined with the spectroscope. The ethereal extract of ergot, if concentrated, absorbs all the refrangible portion of the spectrum beyond D; if the solution is diluted, the spectrum is enlarged, and there appear three absorption bands: the first between D and E, wave-length 538; the second between E and F, wave-length 467. Hoffman agitates the acid ethereal extract with a little solution of sodium bicarbonate, which seizes the coloring-matter of the ergot and takes a fine violet color, whilst the coloring-matters of the flour remain in the ether.

ADDENDA.

In "SCIENCE," March 2, in paper on Amplitude of Vibration of Atoms, for paragraph beginning: "For other atoms than hydrogen," etc., read, "For other atoms than hydrogen, where they have the same energy, their amplitude will vary inversely as the square root of their mass, so that for oxygen the amplitude at 0° will be $\frac{.162}{\sqrt{16}} = .04$ its diameter and its maximum temperature will be $6419 \times 4 = 25676°$ Cent. Also the maximum temperature of the sun would be about 500000° Cent." A. E. D.

THE ODONTORNITHES.—In our last week's notice of the Odontornithes, in the middle of the second paragraph, on page 148, the dental series are said not to "reach the tip of either jaw." In place of "either" substitute "the upper."

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at
229 BROADWAY, NEW YORK.
P. O. Box 3838.

SATURDAY, APRIL 16, 1881.

We present in another column a communication from Professor Alexander Winchell, of the University of Michigan, who, in response to a request from ourselves, has presented a very clear statement of his views relating to some conditions of primitive matter. This subject was introduced in "SCIENCE" by Mr. Larkin (March 26), and followed by Mr. Morris in our last issue.

Much difference of opinion exists on this subject, which is one of the highest interest, and we trust that the open discussion we have permitted may elicit some truth, and lead to a removal of many of the difficulties which underlie this question. Without anticipating our opinion on the merits of the respective arguments which have been adduced or the conclusions to which they lead, we may state that both Mr. Larkin and Mr. Morris, in speaking of gravity, magnetism, heat, light, electricity, motion, etc., etc., appear to make statements which do not accord with the standard authorities on these subjects.

That such difference of opinion should exist on what may be considered fundamental points, should cause no surprise, when even the nomenclature of the physical sciences is in a state of confusion. On this subject we refer our readers to an able article by Professor A. E. Dolbear, published in "SCIENCE" last November (Vol. 1, page 238); this paper demands the careful study of all who would take part in this discussion, and affords a basis on which it may be conducted with profitable results.

We make no apology for introducing this subject to our readers, especially as it has been recently mentioned in popular and scientific books, in connection with philosophical, ethical and theological questions. The objective point of Mr. Larkin's arguments appears to be directed against the Nebular hypothesis of Laplace.

Professor H. Helmholtz, whose lecture on this subject has been recently published by Messrs. Appleton & Co., makes a stout defence of this hypothesis. He asserts that "science is not only entitled, but is beholden, to make such an investigation. For her it is a definite and important question, as it involves the existence of limits to the validity of the laws of nature, which rule all that now surrounds us; the question whether they have always held in the past, and whether they will always hold in the future; or whether, on the supposition of an everlasting uniformity of natural laws, our conclusions from present circumstances as to the past, and as to the future imperatively lead us to an impossible state of things; that is, to the necessity of an infraction of natural laws, of a beginning that could not have been due to processes known to us."

As Mr. Helmholtz observes, to commence such an investigation as to the possible or probable primeval history of our present world considered as a question of science, is no idle speculation, for it is a question as to the limits of its methods, and as to the extent to which existing laws are valid.

We have received several interesting letters on this subject which will be found in our next issue.

THE SEA-SIDE LABORATORY.

The liberality and co-operation of the Woman's Education Association enables the Boston Society of Natural History to announce that a Sea-side Laboratory, under the direction of the Curator, and capable of accommodating a limited number of students, will be open at Annisquam, Mass., from June 5th to September 15th.

Annisquam is situated on an inlet of Ipswich Bay, on the north side of Cape Ann, and is about three and a half miles by coach from the Eastern Railroad Company's station in Gloucester.

The purpose of this Laboratory is to afford opportunities for the study and observation of the development, anatomy and habits of common types of marine animals under suitable direction and advice. There will therefore be no attempt, during the coming summer, to give any stated course of instruction or lectures.

It is believed that such a Laboratory will meet the wants of a number of students, teachers and others *who have already made a beginning in the study of Natural History.* Those who have had some limited experience in a laboratory, or who have attended the practical lessons given by the Teachers' School of Science of the Boston Society of Natural History, are sufficiently qualified to make use of this opportunity.

The work in the Laboratory will be under the immediate care of Mr. B. H. Van Vleck, Assistant in the Museum and Laboratory of the Boston Society of Natural History, a thoroughly competent instructor, and one who has also had long experience in collecting and observing at the sea-side.

Those who would avail themselves of this excellent opportunity to study living objects at the sea-shore should make application to Mr. Alpheus Hyatt, Curator of the Boston Society of Natural History,

THE AMERICAN CHEMICAL SOCIETY.

The April meeting of the American Chemical Society was held on the evening of the 1st inst. There not being a quorum present at eight o'clock, the business of the Society was postponed, and the reading of Dr. A. R. Leed's paper on "Anilo-metallic Compounds" took place. The aniline compounds of Aluminum, Antimony, Barium, Calcium, Cadmium, Chromium, Copper, Cobalt, Bismuth, Mercury, Tin and Zinc were described; how they were prepared and their important characteristics noted. Aniline will not combine with any monivalent element. This paper was a preliminary report of work which Professor Leeds proposes to extend and ultimately publish when he shall have obtained sufficient data. The second paper on the "Action of Concentrated Sulphuric Acid on Lead Alloys" was read by Lucius Pitkin, one of the most talented young chemists of the School of Mines, N. Y. In a paper presented by Mr. James Napier before the Glasgow Philosophical Society, it was held that impure lead was preferable to the pure article for use when in contact with sulphuric acid (see *Chemical News*, Dec. 23, 1880). Mr. Pitkin tried the action of both hot and cold concentrated acids on some forty samples of lead and its alloys. The alloys treated were of lead with antimony, tin, bismuth, cadmium, silver and zinc. In the case of cold acid, 2 sq. in. of each alloy and a sample of pure lead were exposed for 24 hours to the action of 10 c.c. of sulphuric acid at 20° C.; on hot acid the length of exposure was one hour, and his results are best given in the following table, with which his paper terminated.

Average solubility or liability to formation of sulphate of the alloys in terms of lead.

	Cold Acid.	*Hot Acid.*
Lead	1.	1.
" alloyed with Antimony	.81	2.75
" " Tin	1.42	.75
" " Bismuth	1.10	7.69
" " Cadmium	.86	1.10
" " Silver	.87	.93
" " Zinc	1.53	1.10

Considerable discussion followed Mr. Pitkin's paper, in which Dr. Gallatin, Dr. Geyer, Dr, Alsberg, Mr. Herreshoff and Dr. Squibb participated.

Mr. A. E. Hoppick was then elected a regular member of the Society, and Messrs. C. P. Sawyer, A. H. Van Sinderen, and Otto Grote, were proposed for election. Mr. J. H. Stebbins was elected to fill the vacancy caused by the resignation of Dr. Gallatin, as Recording Secretary, and Mr. Herreshoff elected to the positien on the Committee on Nominations which Mr. Stebbins had held.

Mr. Casamajor and Dr. Alsberg reported on behalf of the Committee for the Annual Dinner, and announced that the fifth anniversary dinner of the American Chemical Society would take place at Sieghörtner's restaurant, on Monday, April 18, at 6 P. M.

M. B.

ON SOME PHENOMENA PRESENTED BY VORTEX-RINGS.

PROFESSOR A. E. DOLBEAR, TUFTS COLLEGE, MASS.

1. If one vortex-ring strikes another vortex-ring upon the edge the two rings will bound away from each other as though they were solid elastic bodies, each one vibrating as it recedes.

2. If one vortex-ring overtakes another ring, both moving in the same straight line, and both are of the same size, then the forward one will expand in diameter, and the latter will contract in diameter, and will go through the forward one when each will return to its original dimension. At the same time the forward one will have its velocity retarded while the other will have its velocity increased, and it may overtake the forward one and go through it.

3. If a vortex-ring passes near any light object as, for instance, a silk thread suspended, or better still a small cloud of smoke or ammonium chloride dust, the latter will be seen to be apparently repelled from the front of it but attracted and drawn into the ring from the rear.

4. If a vortex-ring be projected parallel with any surface, and at not too great a distance from the surface, the ring will move in a curved path towards it and strike it.

5. If two vortex-rings are projected so as to start in parallel lines near to each other they will approach each other until they touch, when they may be either broken or else bound away from each other as in the first case above.

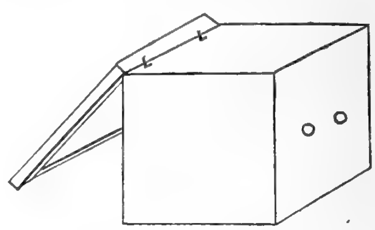
6. If two vortex-rings having the same rate of rotation be started in lines parallel to each other and at not too great a distance apart, they will not only approach each other but *they will combine to form one ring* which continues to move in the same direction.

7. The combination is effected by the breaking of each at the point of contact, and the welding of the opposite parts of each ring to form one ring with twice the diameter.

8. Three rings may in like manner be combined into one.

9. The structure of the vortex-ring is concentric, that is, a cross section of a ring generally shows a series of several concentric circles, with a hollow centre. The middle of the ring appears to be a cylindrical unoccupied space.

As experimental work with such rings is very entertaining as well as suggestive of the behavior of the real atoms of matter, it may be well to give the simple instructions necessary to perfect success.



Provide a cubical box with dimensions about a foot each way, having a swinging back frame, over which is stretched a piece of stout cotton cloth. On the opposite side two or more inch-holes may be bored two inches apart. Pour some strong hydrochloric acid into one saucer, and some strong ammonia water into another. Set the two into the box, and shut down the door. The box will at once be filled with the white fumes, and a tap with the finger upon the cloth back, will send out well-formed rings.

The phenomena 1 to 5, can best be seen by employing only one of the holes, so as to form but a single ring. By striking the cloth a little harder the second time than the first, the second ring may be made to overtake the first, and if it is desirable to exhibit the rings to a room full of people, there should be but a single hole in front, and that one about three inches in diameter; the rings can then be projected with force enough to make them go ten or fifteen feet from the box.

The other phenomena can best be studied by using only small holes, and tapping gently. The rings will come together within a few inches of the box. It seems to be essential that the two rings that combine, should have the same *rate of rotation*, a matter easily secured by forming the two at once in the above described way, but well nigh impossible, if one is formed after the other.

It is sufficient now to remark that the new phenomena described above simulate in a very striking way, what we call gravitation and chemism.

THE CO-EFFICIENT OF SAFETY IN NAVIGATION.*

By Prof. W. A. Rogers, of Harvard University.

It is customary among engineers and architects, in making allowance for the strain to be borne by any part of a structure, to assign to the materials used, a strength sufficient to withstand a strain somewhat greater than the structure is ever likely to be subjected to. By experiment it can be found, for example, what is the "breaking load" of a wooden or iron beam of given dimensions, and an empirical law is established which will give us approximately the breaking load of any beam, when we know the dimensions, material, etc.; but in order to cover all possible differences which may exist in various beams, a *Coefficient of Safety* is either introduced into the formula itself, or is applied to the result obtained from the formula. This co-efficient should be large enough to cover, not only the largest possible deviation between experiment and theory, but also to meet all unforeseen emergencies, such as time and age inevitably bring.

Passing now to the consideration of the term "*Co-efficient of Safety*," as applied to navigation, it is our object to find the limits within which, under ordinary circumstances, a vessel can be located at sea, and then adduce some considerations which will enable us to form an intelligent judgment in regard to the range of error to which observations are liable. The quantity wanted is the average number of miles error in latitude and longitude, which we may fairly charge upon a single observation at sea, under ordinary circumstances. We have then to find the co-efficient by which this number must be multiplied in order to secure absolute safety, as far as safety depends upon human means and exertions.

By an examination of the "British Wreck Register" and the official inquiries made into the causes of disasters at sea, it will be seen that the ratio of loss compared with the increase of tonnage afloat, has for many years been steadily increasing. This inquiry is, therefore not an idle one. It is our purpose to examine only those causes of wrecks which, in a measure, seem to have escaped attention in official investigations. They are :—

I.—Wrecks produced by causes clearly beyond human control.

II.—Wrecks resulting directly or indirectly from over-insurance.

III.—Wrecks caused by the deviation of the compass.

IV.—Wrecks caused by errors of observation at sea.

The first inquiry is an important one, since, if we can find how many wrecks are beyond human control, we ascertain, at the same time, how many are *within* human control. The method of investigation is by the examination of records of Courts of Inquiry for twenty years. Between 1785 and 1813 no less than eight British ships were either wholly or partially disabled by lightning. Of course, vessels lost and never heard from should be added to this list. Between 1864 and 1869 we find from the insurance records that 9999 sailing vessels and 589 steamers, or a total of 10,588, were wrecked. Of this number, the end of 846 is entirely unknown, or one-eighteenth of the whole number. It is probable, therefore, that seven out of ten wrecks occur from preventable causes.

In regard to the second head, it is certain that more insured than uninsured vessels are lost, and in not a few cases it has been possible to convict shipowners of purposely destroying their vessels.

The compass problem is an intricate one, and has never been fully solved, though the researches of Flinders, Barlow, Scoresby, Airy and Harkness have done much to convert great uncertainty into tolerable certainty. The first observations on the variation were by Bond, in 1668. It is well known that the variation of the needle is very irregular. There are yearly, monthly and diurnal inequalities, the diurnal variation being discovered by Graham, in 1722. But the complexity of the problem does not stop here. The tendency of the present time is to build iron ships, and all ships now have more or less iron in their construction. These ships become, to a greater or less degree, themselves great magnets. In wholly iron ships the uncorrected deviation of the needle often amounts to 50°, thus rendering it utterly useless. The Admiralty Law in regard to "swinging" for the variation of the compass is a very clear statement of the case. It reads as follows :

"As the deviation or error of the compass caused by local attraction of the ships becomes changed in amount by any change in the ship's geographical position, and may be entirely reversed in its direction by the ship's proceeding from the Northern to the Southern Hemisphere it is to be invariably tested by azimuth and amplitude observations at sea, and the ship is to be swung for ascertaining the change of error on arrival at a foreign station, and also once a year, and the same is to be inserted in the log book and sent to the Admiralty with the quarterly return for December."

The next important discovery in this connection was by Barlow, who found that all the influence of iron bodies exerted on the compass resides on the surface. This discovery paved the way for Airy's method of correcting compasses, which is by swinging the ship in the usual way, and then correcting the local attraction of the ship by means of permanent magnets of soft iron conveniently placed with respect to the compass. But the most important discovery was made by Dr. Scoresby. He found that every iron ship is itself a magnet, and that it gets its magnetism while building by the inductive magnetism of the earth, the poles of the ship's magnetism depending on the position of the building yard and the direction of the keel in construction. Dr. Scoresby made the voyage of the world in the *Royal Charter*, to test his theory, and found it fully confirmed. Before starting, his compasses were corrected by Airy's plan. On arriving at Melbourne, it was found that a complete inversion of the ship's magnetic polarity had taken place. Every stanchion, every standard, every davit, every mass of iron about the deck had in its upper surface acquired a Northern, instead of a Southern polarity, and the starboard compass had lost nearly one-half of its original errors. On returning to the place of starting in the Northern Hemisphere, and swinging the ship, it was found that a re-inversion had taken place, but the compasses did not quite return to their original deviations, but retained a fraction of their errors. It has since been found that these changes are much greater in steam than in sailing vessels, as shown by observations on board the *Vulcan* (steam), and the *Pandora* (sailing).

In 1852-53, Dr. Scoresby, in a paper before the British Association, showed that there is a sensible difference in the deviation before and after steam is up. It has been said that the compasses of a steam vessel, when light and running before the wind, with a high sea, are practically useless.

More recent experience has shown that the magnetism of an iron ship does not attain its normal condition till some twelve months after launching, and that for some time the variation is very irregular. In the *Great Eastern* a fixed compass changed its deviation nearly 3 points in the first 9 months of service. The observations of Prof. Harkness on board a monitor seem to be conclusive on this point.

We come now to the consideration of the fourth point. As early as 1598, Spain offered a reward of 100,000 crowns for the discovery of a correct method of finding the Longitude at sea. The States of Holland, at an early date, offered a reward of 100,000 florins, and France a reward of 100,000 livres. In 1714 the British Government offered a reward of £10,000 to any one who should

* Abstract of a paper read before the Naval Institute of Annapolis. Prepared under author's direction.

discover a method of finding the longitude at sea within 60 miles, £15,000 if with 45 miles, and £20,000 if within 30 miles. This offer did much to awaken interest in the subject. Though we have long since passed the lowest limit then mentioned, 30 miles, it is doubtful if any two navigators will agree as to what limit we have actually reached. The general testimony of sea-captains, in answer to my inquiries on this point, is that one mile is the ordinary limit within which the co-ordinates of a ship's place can be determined. A few placed the limit at half a mile. Only one navigator, with an experience of 30 years, placed the limit at 5 miles.

Two methods were proposed for the solution of the problem. Morin proposed what is now substantially the Lunar Method, and Maskelyne undertook the solution of the problem by observing the astronomical phenomena, such as eclipses of Jupiter's satellites. On the other hand, mechanicians devoted every energy to the mechanical problem. As the result of these labors, we have two essentially different methods for the determination of Longitude at sea.

I. By Lunar Distances, Occultations and Eclipses of Jupiter's Satellites, &c.

II. By Chronometers, assuming a rate at the beginning of the voyage.

The latter has for a long time been regarded as the more accurate method, but the difficulties to be overcome can be readily imagined, when we consider that even in the determination of the position of fixed observations, in which appliances of the utmost refinement are at hand, the places vary widely from the truth. For example, we find variations in the measured difference of longitude between Greenwich and Paris, as great as 5.5^s, or 1¼ miles, existing previous to the introduction of the telegraphic method of determining, longitudes. The range between the earlier determinations of the difference of longitude between Greenwich and Brussels is 10 miles. Moon Culminations are more accurate than Lunars, but the same in principle. They are the more accurate when the longitude depends upon observations at each station, since the errors of Tables are thus eliminated. From a careful discussion of a long series of observations made at fixed observatories, with the most perfect instruments, it is found that we must expect from the Lunar Method an absolute error of six miles as the result of any number of observations. This corresponds in a general way with Prof. Peirce's investigation. He found that the ultimate limit, when one limb of the moon was observed, to be 0.55^s. "Beyond this," he says, "it is impossible to go with the utmost refinement. By heaping error upon error, it may crush the influence of each separate determination; but it does not diminish the relative height of the whole mass of discrepancy." But the discrepancy between the results for different limbs of the moon often amounts to 10^s in the mean determination of a year. The assumption that the ultimate limit of accuracy is as great as 1^s seems to be a very moderate widening of the limits. I find it to be 2.4^s.

For fixed observatories, using the moon's tabular place, we must expect an error of 3.1 miles, with a range of 12.9 miles. For Lunar Distances with sextant, on land, we must expect an error of 10.2 miles, with a range of 24.2 miles. For Lunar observations at sea these quantities should at least be doubled.

We now come to the subject of chronometers. The sources of errors are:

(*a*) Variations of rate arising from the action of magnetism. Airy's experiments show an extreme variation of 5.8^s in the daily rate of a chronometer, due to terrestrial magnetism.

(*b*) When chronometers are swung on the same support, it is probable that there is a sympathetic action between them, similar to the results recently found by Mr. Christie with the Transit of Venus Clocks.

(*c*) Variation on account of change of barometric pressure. This varies between 0.3^s and 0.8^s per day for every inch of change in the barometer.

(*d*) Variation between land and sea rates. Almost every chronometer will change its rate, when its circumstances, either of rest or motion, are changed. The Boston standard clock of Messrs. Bond & Son, almost invariably has a different rate on Sunday from any other day of the week. So, also, it has a change of rate when the streets are covered to any considerable depth with snow.

(*e*) Variation of rate at sea, on account of change of temperature. Mr. Hartnup, of Liverpool, was the first to give, not only the general rate of a chronometer, but also the rate for different temperatures.

An elaborate discussion of the errors of chronometers, from data collected at the Greenwich Observatory, from chronometric expeditions and from chronometers used in the Merchant and Naval services, the following result has been reached.

At the end of 20 days the navigator must expect an average error of 36 miles. He must look out for an error of 36 × 32 or 11.5 miles, and the amount of his error may prove to be twice this quantity, or 21 miles, all on the supposition that he has an average chronometer, and this is independent of the errors of observation, which must still be added.

We come finally to the consideration of the problem,—How near is it possible to find the place of a ship at sea by astronomical observations, taking into account all the errors to which observations are liable?

For the sake of simplicity we shall consider but one method, the method usually followed, viz.: by measurement of the altitude of the sun with a sextant, at a given time before it comes to the meridian for longitude, and the measurement of its culmination, for latitude.

We must first of all ascertain the magnitude of the errors to which observations with the sextant are liable. The following are some of the errors which we must ordinarily expect in observations with this instrument:

(*a*). Instrumental errors, such as eccentricity, errors of graduation, index error, &c. Errors of this class often exceed one minute of arc, even in a first-class instrument.

(*b*). Errors in noting time. No observer at sea pretends to note the time closer than one second. If we assume this low limit and multiply the co-efficient 3.5 already found, we have an error of nearly one mile.

(*c*). Errors arising from imperfect sea horizon.

(*d*). Errors arising from the use of approximate data.

(*e*). Errors depending on the latitude of the ship and the time of observation. By combination in the same direction, errors of this class may be very large, and, for the most part, they escape the attention of the navigator. The most favorable time for an observation of the sun for longitude is when it is exactly east or west. Here an error of one minute of arc in the observed altitude produces an error of the same amount in the resulting time, but if the observation is made 40 minutes from the meridian, an error of one minute in altitude may produce an error of 6 miles in the resulting position.

(*f*). Errors arising from the error in the estimated run of the ship between the morning and the noon observations.

The data for assigning a limit to the errors of observation with the sextant are as follows:

I. *Observations on Shore.* From a discussion of the observations by Williams in 1793, by Paine in 1831, by various observers at Willets Point in 1869, 1871 and 1872, by Hall and Tupman at Malta and Syracuse, and by Newcomb and Harkness at Des Moines, we find that for *latitude* the average error of observation with the sextant is 8″, that the average range between the greatest and the least results of a given series is 36″, the latter value having a range between 14″ and 59″. The coefficient comes out 4.4. For *time* the average error is 1.1^s, the range is 4.7^s, and the coefficient is 4.4.

II. *Observations at Sea.*

Under this head three distinct investigations have been made, as follows;

(*a.*) From an examination of the results obtained by chronometric longitude expeditions, we find that for a voyage of 15 days the average error is 5.3^s; the range between the greatest and the least results in each series is 18.0^s; the latter value has a range between 1.5^s and 55.0^s, and the coefficient is 3.4.

(*b.*) The longitudes of 36 stations have been determined by various British naval expeditions. The chronometers were rated at the Greenwich Observatory before starting, and the observations for time at the terminal stations were made in the usual way with the sextant. Evidently more than usual care was taken both with the observations and reductions. We find that the average difference between the results obtained by different chronometers is 4.4 miles with a range of 15.1 miles. The average range between the different results for longitude is 5.0 miles with a range of 31.6 miles. The average number of chronometers was 11, and the average duration of voyage was 11 days.

(*c.*) During the spring and summer of 1880 Officer W. H. Bacon, of the Cunard steamer "Scythia," kindly undertook for me a series of systematic observations from which the relative errors could be determined with considerable certainty. A complete series for a single day consisted of five sights at intervals of fifteen minutes, about 8 o'clock in the morning, five sights in the neighborhood of 11 o'clock, and five sights at the corresponding hours in the afternoon. Observations were also made when the ship was in known positions as often as possible.

This series of observations has an exceptional value on account of the conscientious fidelity with which the programme was adhered to and of the skill with which they were made. The relative errors were determined by comparing each position with the mean of the series, the rate being determined both from the morning and afternoon observations and from the log.

The results obtained are found in the following table:

Limits in Miles.	Average Error from Observations at 9^h and 3^h.	Average Error from Log at 9^h and 3^h.	Average Error from Observations at 11^h and 1^h.	Average Error from Log at 11^h and 1^h.	Difference between Observation and Log at 9^h and 3^h.	Difference between Observation and Log at 11^h and 1^h.

QUERY.

A SUBSCRIBER would like to know the best method of mounting Triple phosphate crystals (dry) so as to tack them to the slide without interfering with definition. —Replies invited.

ON THE ACTION OF BACTERIA ON VARIOUS GASES.*

By F. Hatton.

The experiments were made to ascertain the nature of the action exerted by various gases on the life and increase of bacteria, and to observe what influence the bacteria had on the percentage composition of the gases. The bacteria were obtained by shaking fresh meat with distilled water. The aqueous extract was filtered and exposed to the air for twenty-four to thirty-six hours; it was always found to be full of bacteria. A small flask was half filled with mercury, filled up with the bacteria solution, and inverted in a mercury trough. The gas under examination was then passed up, a small glass vessel was introduced under the mouth of the flask, and the whole removed from the trough. The liquid was examined daily as to the condition of the bacteria, the sample being removed by a piece of bent glass tubing having an india rubber joint. After about a week the gas was pumped out by means of a Sprengle and analyzed. Atmospheric air was first tried. The bacteria lived well during the fifteen days of the experiment (T. 15° to 22°). A large absorption of oxygen took place, but it was not replaced by carbonic anhydride; in a second experiment (T. 25° to 26·50) 20 per cent. of the oxygen disappeared, and only 17 per cent. of CO_2 was formed. Pure hydrogen after fourteen days had no action on the bacteria; the gas contained 0.34 per cent. CO_2, 98.94 per cent. H. Pure oxygen after ten days was converted into CO_2 29.98 per cent., O 70.02 per cent. A mixture of CO 46.94 per cent., CO_2 1.27, O 1.27, N 50.51, was next tried after fourteen days; the gas contained CO_2 17.77, CO 0.55, H 7.58, CH_4 2.50, N 71.57. In all of the above cases the bacteria flourished well. Cyanogen was next tried. The solution of meat turned gradually to a thick black fluid. On the fifth day very few bacteria could be seen. From this time, however, they increased, and on the twelfth day were comparatively numerous. On the fifteenth day the gas was analyzed; it contained CN 5.35, CO_2 57.59, O 2.24, N 34.79; a second experiment gave similar results. It appears, therefore, that cyanogen is fatal to bacteria as long as it exists as such, but that it soon decomposes into ammonic oxalate, &c., and that the bacteria then revive, especially in sunlight. Sulphurous anhydride was next tried; the bacteria lived during the fifteen days: the gas contained CO_2 7.87, O 0.00, N 2.13, SO_2 90.10. Similar results were obtained with nitrogen, nitrous oxide, nitric oxide, carbonic anhydride, a mixture of H and O obtained by the electrolysis of water and coal gas. In all cases the bacteria lived well during the experment. The author next experimented with a solution of urea (0.98 per cent.) and phosphate of potash (0.4 per cent.), sowing it with bacteria. The bacteria lived well during the fourteen days of the experiment; small quantities of gas were evolved containing 0.53 per cent. CO_2, 2.64 per cent. O, and 96.82 per cent. N. An experiment was made with spongy iron, air, and bacteria. On the fourth day, all the bacteria had vanished; the air was analysed on the fifth day, and consisted of CO_2 0.26, O 0.00, and N 99.74 per cent. Experiments were also made with acetylene, salicylic acid, strychnine (10 per cent.), morphine, narcotine, and brucine; none of these substances had any effect on the bacteria. On the other hand, phenol, spongy iron, alcohol, and potassium permanganate were very destructive to these microscopic growths.

Mr. W. M. Hamlet said that these experiments confirmed some observations of his own. He had found that bacteria could exist in almost anything—in carbonic oxide, hydrogen, 1 per cent. creosote, phenol, methylamin, methylic alcohol, chloroform. Moreover, Crace-Calvert had shown that they could live in strong carbolic acid. In

* Read before Chemical Society, March 3, 81. This paper obtained for the author the Frankland Prize of £50 at the Institute of Chemistry.

reply to Mr. WARINGTON the speaker said that the acetic acid fermentation went on in the presence of chloroform.

Mr. KINGZETT called attention to the fact that the oxygen was completely used up when the meat infusion was placed in contact with air. He did not think the experiments represented the action of bacteria on gases or of gases on bacteria, but rather the effects of various gases on the mode and extent of ordinary putrefaction.

Dr. FRANKLAND expressed his satisfaction with the results obtained by the author in his laborious research. He must confess that these results had surprised him not a little. The fact that bacteria, which were real organisms and could not be shielded under the term putrefaction, lived and flourished in SO_2, CO, CN, &c., seemed to him very extraordinary, and the question arose whether the germs to which infectious diseases were probably due were not similarly endowed with a power of great resistance to ordinary influences.

Mr. F. J. M. PAGE said that Dr. Baxter had proved that with some fever-producing liquids, their virulence was destroyed by chlorine and sulphuric acid, and that he had seen some experiments at the Brown Institution which led to the same conclusion; so it seemed that, at all events in some cases, the virulence of infective liquids was due to organic matter, essentially different from the bacteria observed by Mr. Hatton.

NOTES ON CHICKEN CHOLERA.

We observe in a recent number of the *Chemical News* that C. T. Kingzett, F. C. S., points out, that, in explaining the protective influence of repeated inoculations with the attenuated virus of chicken cholera, against the more virulent forms of this disease, Pasteur finds it "impossible to resist the idea that the microscopic germ which causes the disease, finds in the body of the animal conditions suitable to its development, and that to satisfy the necessities of its life the germ alters certain substances, or destroys them, which comes to the same thing, whether it assimilates them or whether it consumes them with oxygen borrowed from the blood."

So, again, in cases where complete immunity has been attained, the birds "no longer contain food for the germ."

More striking still is the following passage in reference to chickens which are born proof against cholera:— "Animals in this condition may be said to be born vaccinated for this disease, because the fœtal evolution has not placed in their bodies the proper food of the parasite, or because substances which would serve as such food have disappeared while they were yet young.

Now whether or not we may be prepared to regard the said parasite as the direct cause of the disease, it is remarkable that the reasoning of Pasteur should have culminated in the conclusion upon which Liebig insisted with considerable power.

If we turn to Gregory's (3rd) edition of Liebig's "Animal Chemistry" (p. 205) we find the following passage:—"The condition which determines, in a second individual, his liability to the contagion, is the presence in his body of a substance which by itself, or by means of the vital force acting in the organism, offers no resistance to the cause of change in form and composition operating on it. If this substance be a necessary constituent of the body, then the disease must be communicable to all persons; if it be an accidental constituent, then only those persons will be attacked by the disease in whom it is present in the proper quantity and of the proper composition. The course of the disease is the destruction and removal of this substance: it is the establishment of an equilibrium between the cause acting in the organism which determines the normal performance of its functions and a foreign power by whose influence these functions are altered."

I repeat that to me it seems somewhat remarkable that the investigations and reasoning of two such eminent (and in many matters diametrically opposed) thinkers should have culminated in the same conclusion as regards the conditions of the living body which subject it to, or protect it from, infection.

While, however, it can be readily understood how a profuse growth of parasites could quickly alter or destroy a comparatively large amount of substance—as, for instance, happens in ordinary putrefaction—it does not appear to me so easy to accept Pasteur's reasoning as to his so-called vaccination.

In this inflicted process an attenuated virus is introduced into the body of a chicken which becomes ill but does not die. It does not die because, if Pasteur be correct, the parasites do not sufficiently multiply. Why do they not multiply? It cannot be on account of the insufficiency of the pabulum, for in the large majority of cases where death results this seems to arise from the very profusion of the growth of the parasite when more freely introduced.

Can it be expected, therefore, that even, say, in three successive inoculations the substance which I have here spoken of as pabulum can be entirely removed or destroyed by the very limited number of parasites which are introduced by the inoculations, and which so soon perish in the body? I think this cannot be expected; but if it may be, then the particular substance or substances upon which the parasites prey must be extremely limited in quantity. After all, we are faced with the enormous difficulty of ascertaining the nature of such substance, and the further equally great difficulty of understanding why an undiscovered and undetermined substance should be entirely absent from the bodies in some animals and present in varying proportions in others.

Here we come in contact with the weakest point in the parasitic theory. The immunity from a second attack of an infectious disease of the class in question is simply inexplicable under the parasitic theory. We are forced back to an alternative theory, and that is one of which we at present only recognize the beginnings.

A NEW CORTICAL CENTRE.*

By GRAEME M. HAMMOND, M.D., NEW YORK.

Physician to the Department for Diseases of the Nervous System in the Metropolitan Throat Hospital.

Some six years ago there appeared in the *Centralblatt*, Nos. 37 and 38, a short communication by Betz, embodying an account of certain nerve-cells found by him in the cortex of a region of the brain which he newly named the paracentral lobule. This paper has probably aroused more general attention among neurologists than any other paper of recent times dealing with the structure of the cerebral hemispheres, and this, on account of the anatomical confirmation which the discovery seemed to furnish, of the localization doctrine based on the electrical stimulation of the cortex carried out by Hitzig and Fritsche.

After localizing these cells chiefly in the paracentral lobule and the upper ends of the pre- and post-central gyri of man, stating them to be very few in number in the lower halves of these gyri, Betz proceeds to say, "the constancy of the occurrence of these cells, not only as regards the cortical layer, but also the special convolutions in which they are found, led me to direct my attention to that portion of the brain of animals, and particularly of the dog, on which latter Hitzig and Fritsche obtained such brilliant physiological results. I refer to that lobule which bounds the sulcus cruciatus. Now I found in this very lobule in the dog, cells in similar nests and of a similar shape. With the dog as in man they are distributed in the fourth layer."

Engaged in a study of the ganglionic masses of the forebrain of the cat, an animal on which the experiments of Hitzig and Fritsche have been repeated, and in which

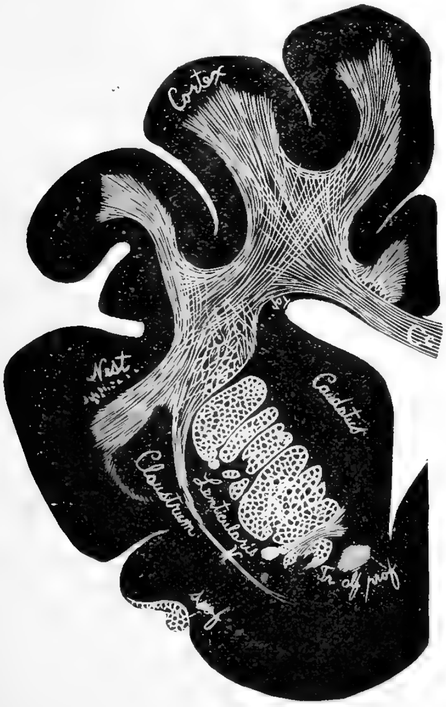
* Read before the New York Neurological Society, February 1, 1881.

the centres have been localized in regions homologous to those of the dog, and in which, furthermore, the architecture of the cortical surface is fundamentally the same, I proceeded to review the question of the localization of the giant-cells.

On the one hand, Betz seemed to argue that the giant-cells, which he claims to have discovered, were motor, because they were found at those points in the dog's brain where Hitzig and Fritsche, by supposed localized electrization, had produced contractions of special groups of muscles. Again, on the other hand, it is apparent that those interested in defending that narrow localization theory, which is such a prominent feature in the teachings of Charcot and Ferrier, have found one of their strongest supports in the anatomical discoveries of Betz.

Let us suppose then, for the sake of argument, that it be granted that larger cells mean motor centres for larger muscles; taking up the localizationists on their own ground we will examine the location of these giant-cells in a cat's brain, which only differs in a single exception from the dog's, and is therefore a fit subject for study. In fact, the cat's brain has the advantage of being somewhat simpler.

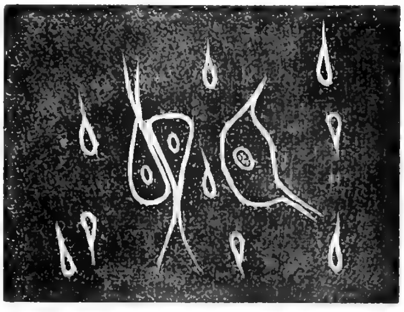
The results I have obtained are based upon the study of the cortical area of the two hemispheres of one cat. One hemisphere was cut as a whole into some seventy-five sections, from different altitudes transversely to the cerebral axis. The other was separated into eleven segments, and each segment cut into a number of thin sections. The series of sections derived from the first hemisphere served as a sort of topographical guide for the location of anything that might be found in the second.



I found that the giant-cells are not confined to localized areas as Betz claims. I find that they are not as numerous near the sulcus cruciatus as they are much posterior to that region. I have even found giant-cells not very far from the base of the brain, but I found the largest group of the largest cells in a place not yet indicated on any of the charts of the localizationists as an unquestionable motor point. In the accompanying woodcut the position of the nest of cells that I have discovered is accurately demonstrated. These cells are ovoid, circular, and sub-pyramidal in shape, and possess a round nucleolated nucleus situated about the centre of the cell. Each cell has from two to six visible processes. The ovoid cells are much the larger, their long diameter measuring from 0.08 mm. to 0.12 mm.; and their short diameter from 0.05 mm. to 0.06 mm. The circular and subpyramidal cells measure from 0.07 mm. to 0.08 mm. in diameter. The nuclei of all the varieties are of the same size, and measure 0.03 mm. in diameter. I only succeeded in finding them in one locality, but found them very numerous in that area. They are situated in the first primary arched gyrus, between the Sylvian and anterior Sylvian fissures. Ferrier, in his "Functions of the Brain" indicates a "centre" on the frontal division of the fourth external convolution, where, he says, he has observed, on irritating this centre, "a divergence of the lips so as to partially open the mouth." This centre approaches nearer in position to the one I have discovered than any other. With this study I was enabled to locate the chief foci for condensation of the giant-cells, of the shape known to Betz and Mierzejewski. These are pyramidal in shape, with a central round nucleus, and measure from 0.09 mm. to 0.12 mm. in length, and from 0.03 mm. to 0.04 mm. in width at the base. Their nuclei measure 0.02 mm. in diameter. The following woodcut shows how two of Betz's largest cells can be placed so that their conjoined areas are only equal to the areas of one of the ovoid cells such as I have described.

I regard the term "area of large cells" as inaccurate. The large cells are scattered more or less widely over the brain-surface, and it would be better to speak of "foci" when they are concentrated in larger numbers than elsewhere.

The giant-cell of Betz is not a new discovery. It is not a thing by itself distinct from the other pyramidal cells of the cortex. On the contrary, both in the human cor-



tex and in the cat, every transition from the average-sized cell of the third frontal layer to the giant-cell can be traced. I would also call attention to the fact that Betz states "these cells to be in nests" and not uniformly distributed in one layer, but I have seen, in one section from the paracentral lobule of the human brain, giant-cells arranged in regular order like soldiers on parade, for a distance of one-third of an inch.

Taking the deductions, which have been based upon the existence of these cells, on their merits, we find that those who have relied on this demonstration for the support of the theory of motor centres, are reduced to a number of predicaments. 1. That the largest giant-cells have been found in the brain of carnivora where no motor centre has been clearly demonstrated, and near which only small muscles are supposed to receive their cortical innervation. 2. That if, after all, this is a motor centre, that the method of localization was incompetent to detect it. I have limited myself this evening to this single fact. I need not say that the giant-cell was known to Meynert, although its locality was not accurately described by him. He claimed that the larger gyri of the frontal lobe contained the largest cells. On the other hand, cells as large as the giant-cells can be seen through the entire occipital lobe, according to this observer, in

the two white strata, and were described by him by the name of "solitary cells." I trust at no distant date to review the entire question of the distribution of large cortical cells with measurements and to submit them to the society.

For the present I think the existence of the large cortical cell group which I have described, shows conclusively that before the existence of large cells can be considered a demonstration of the correctness of functional localization, a more extended study must be made.

THE UNITY OF NATURE.

By the Duke of Argyll.

VII.

ON THE MORAL CHARACTER OF MAN CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

(Continued).

It may be well, before proceeding farther in this branch of our inquiry, to retrace for a little the path we have been following, and to identify the conclusions to which we have been led.

In the first place, we have seen that the sense of obligation considered in itself—that is to say, considered apart from the particular actions to which it is attached—is a simple and elementary conception of the mind, insomuch that in every attempt to analyze it, or to explain its origin and growth, this absurdity can always be detected,—that the analysis or explanation universally assumes the previous existence of that very conception for which it professes to account.

In the second place, we have seen that, just as Reason, or the logical faculty, begins its work with the direct perception of some simple and elementary truths, of which no other account can be given than that they are intuitively perceived, or, in other words, that they are what is called "self-evident," so in like manner the Moral Sense begins its work with certain elementary perceptions and feelings in respect to conduct, which arise out of the very nature of things, and come instinctively to all men. The earliest of these feelings is the obligation of obedience to that first Authority the rightfulness of which over us is not a question but a fact. The next of these feelings is the obligation of acting towards other men as we know we should like them to act towards ourselves. The first of these feelings of obligation is inseparably associated with the fact that all men are born helpless, absolutely dependent and subject to Parents. The second of these feelings of obligation is similarly founded on our conscious community of nature with other men, and on the consequent universal applicability to them of our own estimates of good and evil.

In the third place, we have seen that this association of the higher powers of Man with rudimentary data which are supplied by the facts of Nature, is in perfect harmony with that condition of things which prevails throughout Creation,—the condition, namely, that every creature is provided from the first with just so much of instinct and of impulse as is requisite to propel and guide it in the kind and to the measure of development of which its organism is susceptible, leading it with unfailing regularity to the fulfillment of the law of its own being, and to the successful discharge of the functions assigned to it in the world.

In the fourth place, we have seen that the only really exceptional fact connected with Man is—not that he has faculties of a much higher kind than other creatures, nor that these faculties are susceptible of a corresponding kind and measure of development—but that in Man alone this development has a persistent tendency to take a wrong direction, leading not towards, but away from, the perfecting of his powers.

In the last place, we have seen that as a matter of fact, and as a result of this tendency, a very large portion of Mankind, embracing almost all the savage races, and large numbers of men among the most civilized communities, are a prey to habits, practices, and dispositions which are monstrous and unnatural—one test of this unnatural character being that nothing analogous is to be found among the lower animals in those spheres of impulse and of action in which they have a common nature with our own; and another test being that these practices, habits, and dispositions are always directly injurious and often even fatal to the race. Forbidden thus and denounced by the highest of all authorities, which is the authority of Natural Law, these habits and practices stand before us as unquestionable exceptions to the unity of Nature, and as conspicuous violations of the general harmony of Creation.

When, however, we have come to see that such is really the character of these results, we cannot be satisfied with the mere recognition of their existence as a fact. We seek an explanation and a cause. We seek for this, moreover, in a very different sense from that in which we seek for an explanation and a cause of those facts which have the opposite character of being according to law and in harmony with the analogies of Nature.

With facts of this last kind, when we have found the place into which they fit in the order of things, we can and we do rest satisfied as facts which are really ultimate—that is to say, as facts for which no other explanation is required than that they are part of the Order of Nature, and are due to that one great cause, or to that combination of causes, from which the whole harmony and unity of Nature is derived. But when we are dealing with facts which cannot be brought within this category,—which cannot be referred to this Order, but which are, on the contrary, an evident departure from it,—then we must feel that these facts require an explanation and a cause as special and exceptional as the results themselves.

There is, indeed, one theory in respect to those mysterious aberrations of the human character, which, although widely prevalent, can only be accepted as an explanation by those who fail to see in what the real difficulty consists. That theory is, that the vicious and destructive habits and tendencies prevailing among men, are not aberrant phenomena at all, but are original conditions of our nature, —that the very worst of them have been primitive and universal, so that the lowest forms of savage life are the nearest representatives of the primordial condition of the race.

Now, assuming for the present that this were true, it would follow that the anomaly and exception which Man presents among the unities of Nature is much more violent and more profound than on any other supposition. For it would represent the contrast between his instincts and those of the lower animals as greatest and widest at the very moment when he first appeared among the creatures which, in respect to these instincts, are so superior to himself. And it is to be observed that this argument applies equally to every conceivable theory or belief as to the origin of Man. It is equally true whether he was a special creation, or an unusual birth, or the result of a long series of unusual births each marked by some new accession to the aggregate of faculties which distinguish him from the lower animals. As regards the anomaly he presents, it matters not which of these theories of his origin be held. If his birth, or his creation, or his development, whatever its methods may have been, took place after the analogy of the lower animals, then, along with his higher powers of mind, there would have been corresponding instincts associated with them to guide and direct those powers in their proper use. It is in this essential condition of all created things that Man, especially in his savage state, presents an absolute contrast with the brutes. It is no explanation, but, on the contrary, an insuperable increase of the difficulty,

to suppose that this contrast was widest and most absolute when Man made his first appearance in the world. It would be to assume that, for a most special and most exceptional result, there was no special or exceptional cause. If Man was, indeed, born with an innate propensity to maltreat his women, to murder his children, to kill and eat his fellow, to turn the physical functions of his nature into uses which are destructive to his race, then, indeed, it would be literally true that

" Dragons of the prime,
That tare each other in their slime,
Were mellow music matched with him."

It would be true, because there were no Dragons of the prime, even as there are no reptiles of the present age —there is no creature, however terrible or loathsome its aspect may be to us, among all the myriads of created things—which does not pass through all the stages of its development with perfect accuracy to the end, or which, having reached that end, fails to exhibit a corresponding harmony between its propensities and its powers, or between both of these and the functions it has to perform in the economy of Creation. So absolute and so perfect is this harmony, that men have dreamed that somehow it is self-caused, the need and the requirement of a given function producing its appropriate organ, and the organ again reacting on the requirement and the need. Whatever may be the confusion of thought involved in this idea, it is at least an emphatic testimony to the fact of an order and an adjustment of the most perfect kind prevailing in the work of what is called Evolution, and suggesting some cause which is of necessary and universal operation. The nearer, therefore, we may suppose the origin of Man may have been to the origin of the brutes, the nearer also would his condition have been to the fulfillment of a law which is of universal application among them. Under the fulfillment of that law the higher gifts and powers with which Man is endowed would have run smoothly their appointed course, would have unfolded as a bud unfolds to flower,—as a flower ripens into fruit,—and would have presented results absolutely different from those which are actually presented either by the savage or by what is called the civilized condition of Mankind.

And here it may be well to define, as clearly as we can, what we mean by civilization, because the word is very loosely used, and because the conceptions it involves are necessarily complex. Usually it is associated in our minds with all that is highest in the social, moral, and political condition of the Christian nations as represented in our own country and in our own time. Thus, for example, respect for human life, and tenderness towards every form of human suffering, is one of the most marked features of the best modern culture. But we know that this sentiment, and many others which are related to it, were comparatively feeble in the case of other societies which, nevertheless, we acknowledge to have been very highly civilized. We must, therefore, attach some more definite and restricted meaning to the word, and we must agree to understand by civilization only those characteristic conditions which have been common to all peoples whom we have been accustomed to recognize as among the governing nations of the world. And when we come to consider what these characteristics are, we find that though complex, they are yet capable of being brought within a tolerably clear and simple definition. The Latin word *civis*, from which our word civilization comes, still represents the fundamental conception which is involved. The citizen of an imperial City,—the subject of an imperial Ruler,—the member of a great State,—this was the condition which constituted the Roman idea of the rank and status of civilization. No doubt many things are involved in this condition, and many other things have come to be associated with it. But the essential elements of the civilized condition, as thus defined or understood, can readily be separated from others which are not essential. An extended knowledge of the useful arts, and the possession of such a settled system of law and government as enables men to live in great political communities, these are the essential features of what we understand by civilization. Other characteristics may co-exist with these, but nothing more is necessarily involved in a proper understanding, or even in the usual application of the word. In particular, we cannnot affirm that a civilized condition involves necessarily any of the higher moral elements of character. It is true, indeed, that no great State, nor even any great City, can have been founded and built up without courage and patriotism. Accordingly these were perhaps the most esteemed virtues of antiquity. But these are by no means confined to civilized men, and are, indeed, often conspicuous in the savage and in the barbarian. Courage, in at least its lower forms, is one of the commonest of all qualities; and patriotism, under the like limitation, may almost be said to be an universal passion. It is in itself simply a natural consequence of the social instinct; common to Man and to many of the lower animals—that instinct which leads us to identify our own passions and our own sympathies with any brotherhood to which we may belong,—whatever the associating tie of that brotherhood may be,—whether it be morally good, bad, or indifferent. Like every other instinct, it rises on its moral character in proportion as it is guided by reason and by conscience, and in proportion as, through these, it becomes identified with duty and with self-devotion. But the idea of civilization is in itself separate from the idea of virtue. Men of great refinement of manners may be, and often are, exceedingly corrupt. And what is true of individuals is true of communities. The highest civilizations of the heathen world were marked by a very low code of morals, and by a practice even lower than their code. But the intellect was thoroughly cultivated. Knowledge of the useful arts, taste in the fine arts, and elaborate systems both of civil polity and of military organization, combined to make, first Greek, and then Roman, civilization, in such matters the basis of our own.

It is, therefore, only necessary to consider for a moment these essential characteristics of what we mean by civilization, to see that it is a conception altogether incongruous with any possible idea we can form of the condition of our first parents, or, indeed, of their offspring for many generations. An extended knowledge of the useful arts is of necessity the result of accumulation. Highly organized systems of polity were both needless and impossible before settled and populous communities had arisen. Government was a simple matter when the "world's gray fathers" exercised over their own children the first and the most indisputable of all authorities.

It is unfortunate that the two words which are habitually used to indicate the condition opposite to that of civilization are words both of which have come to mean a great deal more than mere ignorance of the useful arts, or a merely rudimentary state of law and government. Those two words are barbarism and savagery. Each of these has come to be associated with the idea of special vices of character and of habit, such as cruelty and ferocity. But "barbarian," in the classical language from which it came to us, had no such meaning. It was applied indiscriminately by the Greeks to all nations, and to all conditions of society other than their own, and did not necessarily imply any fault or failure other than that of not belonging to the race, and not partaking of the culture which was then, in many respects at least, the highest in the world. St. Paul refers to all men who spoke in any tongue unknown to the Christian communities as men who were "to them barbarians." But he did not associate this term with any moral faults, such as violence or ferocity; on the contrary, in his narrative of his shipwreck on the coast of Malta, he calls the

natives of that island "barbarous people" in the same sentence in which he tells us of their kindness and hospitality. This simple and purely negative meaning of the word barbarian has been lost to us, and it has become inseparably associated with characteristics which are indeed common among uncivilized nations, but are by no means confined to them. The epithet "savage," of course, still more distinctly means something quite different from rude, or primitive or uncultivated. The element of cruelty or of ferocity is invariably present to the mind where we speak of savagery, although there are some races—as for example, the Eskimo—who are totally uncivilized, but who, in this sense, are by no means savage.

And this may well remind us that, as we have found it necessary to define to ourselves the condition which we are to understand by the word civilization, so it is not less essential to define and limit the times to which we are to apply the word primeval. For this word also is habitually used with even greater laxity of meaning. It is often employed as synonymous with primitive, and this again is applied not only to all times which are prehistoric, but all conditions even in our own age which are rude or savage. There is an assumption that,the farther we go back in time, there was not only less and less extensive knowledge of the useful arts,—not only simpler and simpler systems of life and polity,—but also that there were deeper and deeper depths of the special characteristics of the modern savage. We have, however, only to consider what some of these characteristics are, to be convinced that although they may have arisen in early times, they cannot possibly have existed in the times which were the earliest of all. Things may have been done, and habits may have prevailed, when the multiplication and dispersion of Mankind had proceeded to a considerable extent, which cannot possibly have been done, and which cannot possibly have prevailed when as yet there was only a single pair of beings "worthy to be called" man and woman, nor even when as yet all the children of that pair knew themselves to be of one family and blood. The word primeval ought, if it is to have any definite meaning at all, to be confined to this earliest time alone. It has already been pointed out, that on the supposition that the condition of primeval man approximated to the condition of the lower animals, that condition could not have been nearer to, but must, on the contrary, have been very much farther removed from the condition of the modern savage. If, for example, there ever was a time when there existed on one spot of earth, or even on more spots than one, a single pair of human beings, it is impossible that they should have murdered their offspring, or that they should have killed and eaten each other. Accordingly it is admitted that cannibalism and infanticide, two of the commonest practices of savage and of barbarous life, cannot have been primeval. But this is a conclusion of immense significance. It hints to us, if it does no more, that what is true of one savage practice may possibly be true of others.

(To be Continued.)

ASTRONOMY.

COMPARISON STARS:—Under this heading Mr. Dreyer, in the last number of *Urania*, makes a most excellent "Suggestion to Astronomers" upon a matter which, of late, attracted some little attention. It is to be hoped that other observers will follow the example set at the Dunsink Observatory. Mr. Dreyer's "suggestion" is as follows:

"In spite of the numerous star-catalogues in the hands of observers of minor planets and comets, it frequently happens that a well-determined place for a comparison star cannot be found in any catalogue. Many stars have therefore to be re-observed, and much time is no doubt lost by a number of observers, each having to determine the places of a few stars, which, if put together in one working list could be observed by one person with but little trouble.

It would evidently be an advantage if an astronomer, having at his disposal a good transit circle, would, for a time, endeavor to determine the places of all the comparison stars recently used and requiring re-observation.

In accordance with this scheme, I shall, until further notice (with the concurrence of Dr. Ball) be glad to determine with the Dunsink Transit Circle the places of any comparison stars north of —20° Declination not found in modern catalogues, and recently used in observations of minor planets or comets. The mean places, based on the Fundamental Catalogue of the 'Astronomische Gesellschaft,' will be worked out and published as soon as practicable."

THE SOLAR PARALLAX.

M. Faye has recently communicated to the Paris Academy of Sciences (*Comptes Rendus Tome XCII., No. 8*), an interesting paper upon the actual state of our knowledge of the sun's parallax. Remarking that there is no other constant in science whose determination depends upon such a large number of entirely independent results, he subdivides the various values assigned for the sun's mean parallax, as follows:

Geometrical Methods 8.82"	8.85"	by Mars (Cassini's method)	Newcomb
	8.78	by Venus, 1769 (Halley's method)	Powalky
	8.81	by Venus, 1874 "	Tupman
	8.87	by Flora, (Galle's method)	Galle
	8.79	by Juno "	Lindsay
Mechanical Methods 8.83"	8.81	by the lunar inequality (Laplace's method)	———
	8.85	by the monthly equation of the earth	Leverrier
	8.83	by the perturberations of Mars and Venus	Leverrier
Physical Methods 8.81"	8.799	velocity of light (Fizeau's method)	Cornu
	8.813	" " (Foucault's method)	Michelson

In regard to the value 8.85" obtained by Cassini's method, M. Faye says that Mars has always given values for the solar parallax somewhat too large. The first value 8."81 obtained by mechanical methods was calculated by adopting for the coefficient of the inequality 125.2", the mean between the result of Airy from the Greenwich observations, and that of Newcomb from the Washington observations, taking for the moon's parallax 57′ 2.7", and for her mass $\frac{1}{80.8}$. By the second of the "mechanical methods" Leverrier found 8."95, which was afterwards reduced to 8.85" by Stone upon correcting two slight errors in the computation. The value from the perturbations of Venus and Mars, assigned by Leverrier was 8.86", but one of the numbers requiring a small correction, it is reduced to 8.83". Michelson having overcome all the difficulties in Foucault's method, found for the velocity of light 2,999.40 kilom. ± 100 kilom. Using Struve's constant of aberration the corresponding values of the parallax are 8.799" and 8.813", as above. The general mean is 8.82", to which M. Faye attributes a probable error of ± 0.016". Although each of the values may be effected by systematic error, nevertheless, since the causes of error are varied, and without the least possible connection, these errors must be to a great degree eliminated, as well as the accidental errors.

The following conclusions are reached:

1. That the physical methods are superior to all others, and should be adopted.

2. That the value of the solar parallax, 8.813" (by physical methods), is now determined to about $\frac{1}{100}$ of a second.

3. That the seven astronomical methods converge more and more towards that value, and tend to confirm it, without equalling it in precision.

This fact does not diminish, however, the great importance of observations upon the coming transit of Venus, to which we can now bring to our aid the most effective of photographic apparatus. W. C. W.

WASHINGTON, D. C., April 14, 1881.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE:"

PRIMITIVE STAGES OF COSMICAL EVOLUTION.

Some correspondence which has recently appeared in your columns seems to render it proper to offer a brief synopsis of my conception of the primitive modes of existence of cosmical matter. Supposing luminous cosmical matter to be intensely heated, there is no good reason for assuming this to be absolutely a first condition. It is undoubtedly a remote and primitive condition, which may be assumed as a stage from which cosmical development proceeds. But, in the light of recent science, we may reasonably seek for earlier stages at which cosmical matter existed in a cold and non-luminous state. In these stages we may conceive it either as atomically subdivided and dissociated, or as partly in a condition of molar aggregation, and perhaps of chemical combination. I am inclined to think, with Laplace and Kant, that space is abundantly stocked with cosmical matter in a crude and unformed state. I see no ground for assigning any limit to the state of subdivision in which some of it may exist. I see no satisfactory ground for assuming as Macvicar and others have done, that it emerges from an ethereal condition, nor for denying it. I do not imagine it to possess a temperature different from that of the space in which it floats—if, indeed space, which is not conditioned by matter, can be said to possess a property, which we only know as an affecton of matter.

But there is a principle of gravitation in the universe, however we may explain it, which is ever beginning the aggregation of the ultimate elements of cosmical matter, and ever uniting these aggregations into masses larger and larger. We have made the acquaintance of some of these masses, large and small, in meteoric stones and millions of meteoroids, which become kindled only by friction with our atmosphere. It has been shown that several meteoroidal trains identify themselves with well-known cometary existences. It has been suggested that a rain of cosmical matter has pelted the minute satellites of Mars until the angular orbital motion of the inner one exceeds the axial motion of the planet. The collisions of molecules and masses must result in the evolution of heat. This, within certain limits of temperature, would promote the chemical union of atoms previously dissociated. But the impact of larger masses and groups of masses and molecules would undoubtedly develop sufficient heat to vaporize matter, and even to reproduce a state of dissociation. Such events would characterize the history of any vast region of space in which cosmical atoms should have become relatively approximated. They are in process of falling together. This is the condensation of the cosmical swarm. It may proceed, as Sir William Herschel conceived, until the successive stages of nebular condensation have been passed, when the swarm arrives at the condition of a sun. But it is well-nigh impossible for two cosmical masses to come together without producing rotation. The constituent portions of a nebula must probably rotate, and the nebula as a whole must, in most cases, exist in a state of rotation. Such a nebula was the starting point of Laplace, and was recognized as an actual contingency by Sir William Herschel.

But I do not conceive a fully formed and characteristic nebula as necessarily in a state of complete gaseity. The perpetual collision of hard parts might vaporize sufficient matter to occupy the intervening spaces and afford the characteristic spectral results.

As long as the nebula remains in process of condensation through central gravitation, the evolution of heat must continue. But there is a juncture at which rise of temperature must cease. That is reached when the elastic forces equilibrate the attractive. From this point, condensation developes heat, but some more is lost than is acquired, and the mass continually subsides in temperature. It is only the loss of an excess of heat which now permits the progressing condensation. Cooling is the limiting condition of condensation; and to assert a rising or a constant temperature is to assume that a condition may be surpassed by the effect of that which it conditions and measures. It is a virtual denial of the conservation of energy and of the equation of cause and effect.

In this view of cosmical beginnings, nebular heat is preceded by motion, and the cause of motion is what we call gravity. If, as Le Sage maintained, gravity is only the effect of the impact of a storm of ultramundane corpuscles, then our explanation ends at last in motion for which we cannot invoke gravity as an ultimate physical cause. Metaphysically speaking, such must be the issue of all explanations. There is a necessary *ultima thule* in the realm of thought. We are no nearer an absolute explanation at one stage of cosmical development than at any other The remotest term reached must always stand scientifically unexplained.

I began by supposing luminous nebular matter intensely heated. There are many indications that such is its condition. The bright spectral lines and the analogy of the envelopes of the solar and stellar bodies are strongly suggestive. The rational continuity of cosmical development, leading our thoughts backward from an incrusted world through all conceivable stages, to an incandescent vapor or possibly gas, enforces the conviction of high nebular temperature. But, on the contrary, the very limited number of nebular bright lines spectroscopically revealed proclaims a fundamental condition widely different from that in the sun and fixed stars. It might be suggested that this indicates not only elemental dissociation, but an ulterior resolution, as Lockyer maintains, into one or two sole sorts of world-stuff; but it may also be suggested that the phenomenon is so divergent from the results of any terrestrial verifications that we are left without any substantial ground for inference. The nuclei of comets give also a few bright spectral lines. When the comet is near its perihelion it is not difficult to admit, in some cases, that the spectrum reveals a volatilized condition; but when a body so tenuous as to transmit star-light has retired from perihelion, it is difficult to believe that a gaseous condition is still the effect of high incandescence. The identification of cometary and cold meteoroidal trains, if it has truly been done, throws doubt on the assumed heat of even the nuclear portions of a comet remote from the sun; and yet even here it is supposable that perpetual collision of cold hard parts disengages sufficient heat to create a common gaseous medium. Finally, the meteoric streak of light left sometimes fifteen to thirty minutes after the fall and dissipation of the meteor, cannot be a case of heated luminosity. Heat vaporizes the meteoroid; but it is then a train of minutely divided particles exposed to almost instantaneous refrigeration. A few grains of matter strewn along a path twenty miles in extent, in the cold atmosphere, cannot retain luminosity as a consequence of high temperature. We might cite the streamers of the *aurora borealis*, and the Geisslerian discharges, and Crooke's radiant matter, and the general phenomena of phosphorescence as further reminders that intense heat is not the only cause of luminosity, and suggestions that nebular light *may* not be exclusively the light of thermal incandescence.

ALEXANDER WINCHELL.

UNIVERSITY OF MICHIGAN, *April* 8, 1881.

BOOKS RECEIVED.

SIGHT: An Exposition of the Principles of Monocular and Binocular Vision, by JOSEPH LE CONTE, LL.D., Professor of Geology and Natural History in the University of California.—D. Appleton & Co. New York, 1881.

This is another of those books specially prepared to bring wiihin the reach of the general reader, some of the most interesting but complicated problems of science.

In the present case Professor Le Conte has attempted the double task of writing a work for the general public, which should also be found profitable reading for even the most advanced specialist. This would appear to be an embarrassing operation even with a popular subject, but with one so purely technical as optics the difficulties of the author must have been greatly increased.

To accomplish this programme with success, Professor Le Conte has divided his subject into two parts; the first treating, in an elementary manner, the anatomy and construction of the human eye, and the various theories involved in vision; and also a second part addressed to the specialist, in which some of the disputed points in Binocular vision are treated in detail.

Professor Le Conte, in speaking of the wonderful mechanism of the human eye, describes it as a masterpiece of Nature, whereas it is well known that many authors have been far less enthusiastic in its praise.

To show how differently two authors may treat the same subject even from the same point of view, let us compare what Professor Le Conte and Dr. H. Newell Martin says, as to the comparison of the human eye with a microscope objective, for curiously enough they both select the same object for this purpose, the former in the work now under review, and the latter in "The Human Body," a book recently received in our office, a notice of which is in preparation.

Professor Le Conte remarks, * "We see, then, that the mode of adjustment of the eye is somewhat like that of the Microscope." "Like the Microscope, but how infinitely superior."

Whereas, Dr. Martin observes: "The eye, though it answers admirably as a physiological instrument, is by no means as perfect optically; not nearly so good, for example, as a good Microscope objective." † Again Professor Le Conte, while indeed speaking of "defects of the eye as an instrument," refers such imperfections to a condition of disease or malformation, or at least to eyes which are not "normal or perfect," and specially mentions Myopy or Brachymetropy, Presbyopy, Hypermetropy and Astigmatism. Whereas, Dr. Martin points out defects of the human eye, which appear to be the normal condition of human vision, and exist "even in the best of eyes"—such as the "reflecting surfaces of our eyes not even being truly spherical, especially in the case of the cornea," and that "few persons are able to see equally clearly, at once, two lines crossing one another at right angles," this defect, when existing in a marked degree, causing serious trouble, amounting to disease, and known as "*astigmatism*."

In regard to the first part of the work, we may state that rarely has the subject been before treated in a manner so likely to realize in the mind of the student all that it is necessary to know in regard to the vision of man. The author's descriptions are so clear that to misconstrue them is impossible. Excellent illustrations are given, the majority being diagrams prepared by Professor Le Conte.

In regard to the more technical parts of the work relating to Binocular Vision, we find a difficulty in giving a resumé without diagrams, which it is not possible to present with this notice, but we trust we have aroused sufficient interest in this book to induce those studying the question to make direct use of Professor Le Conte's work, where the whole subject is explained.

Professor Le Conte's own views, however, on Binocular vision may be given, which are expressed in the following words:

"All objects or points of objects, either beyond or nearer than the point of sight, are doubled but *differently*. The former homonymously, the latter heteronymously. The double images in the former case are united by *less* convergence, in the latter case by *greater* convergence of the optic axes. Now the observer knows *instinctively and without trial*, in any case of double images, whether they will be united by greater or less optic convergence, and therefore never makes a mistake, or attempts to unite by making a wrong movement of the optic axes. In other words, *the eye (or the mind) instinctively distinguishes homonymous from heteronymous images, referring the former to objects*, successive combination of the different parts of the object or scene, or pictures, as maintained by Brücke." ‡

Professor Le Conte claims that this work "meets a real want, and fills a real gap in scientific literature;" in this assertion we heartily concur.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

A PROBLEM IN OPTICS.

To the Editor of "SCIENCE:"

Will some of your correspondents answer the following questions, not from any tables given in books, but by original computation or observation. Given a plate of crown glass, index of refraction 1.525, with parallel surfaces, a ray of light incident on the under-surface 38° from the normal.

What will be the direction of the ray *in the glass*? What will be its direction of emergence from the upper surface into air? What its direction into water? What percentage of the light will be lost by reflection from the under surface of the plate? What will be lost from the upper surface?

If the light is incident 45° from the normal, what is the answer to each of the above questions?

As each color of the spectrum has a different degree of refraction the medium ray should as usual be taken for computation.

The thickness of the plate cannot affect the refraction *in* the glass, only the point where the ray reaches the upper surface. CARL REDDOTS.

OZONE is absorbed in a solution of arsenious acid to which a little neutral potassium iodide has been added. The excess of arsenious acid is estimated with standard iodine solution. 1. Ozone is a constituent of the higher atmosphere to a much larger extent than near the earth's surface. 2. Ozone is destroyed by contact with the gases and organic matter in a moist atmosphere, as near the earth's surface, and that the collection of ozone from the air is attended by the destruction of it to a large extent. 3. The absorptive power of the ozone in the air is quite sufficient to account for the limitation of the solar spectrum. 4. The blue tint of the atmosphere is largely due to ozone.—W. N. HARTLEY.

ERRATA.

How to obtain the Brain of the Cat, (Wilder).—Correction: Page 158, second column, line 7, "grains," should be "grams;" page 159, near middle of 2nd column, "succesily," should be "successively;" page 161, the number of Flower's paper is 3.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, APRIL 23, 1881.

The growth of abstract science in this country is perhaps no better illustrated than by the advance which has been made of late years in the various departments of mathematics. It is only a few years since Prof. Peirce was about the only person in the United States who held a position among the original mathematicians of the world, while to-day there are in this country a number of persons whose writings are destined to rank among the classics, and a journal of mathematics of the highest rank is published under the auspices of the Johns Hopkins University and sustained almost entirely by American contributors. Among the best of the abstract writers referred to is Mr. William Ferrel, who has been hitherto best known by his tidal researches, but is now engaged in investigations on the mathematical principles of meteorology. His latest work, just published by the Coast Survey, is now before us, and although nominally consisting only of researches on Cyclones, Waterspouts and Tornadoes, is in reality a valuable contribution to the theory of storms in general.

The Board of Directors of the Ohio Mechanics' Institute have organized a "*Department of Science and Arts*" for the purpose of increasing the usefulness of the Institution. A Section of Mechanics and Engineering under the chairmanship of Professor H. T. Eddy, and one of Chemistry under Professor F. W. Clark, have been arranged. Meetings for the public discussion of scientific subjects will be held once a month, and various other arrangements are in progress which will contribute to the success of the present attempt to provide increased facilities for technical and scientific education for the youths of Cincinnati.

SCIENTIFIC SOCIETIES OF WASHINGTON.

The Biological Society, Washington.—Since our last report the following papers have been read: "Roan Mountain, North Carolina, and its Flora," by Prof. J. W. Chickering, Jr.; "Notes on the Flowering of *Solanum rostratum* and Cassia chamaecrista, with illustrations," by Prof. J. E. Todd; "A Critical Review of Günther's Ichthyology," by Prof. Theodore Gill; "On the Mortality of Marine Animals in the Gulf of Mexico," by Mr. Ernst Ingersoll: "A Statistical View of the Flora of the District of Columbia," by Prof. Lester F. Ward. It is to be regretted that the absence of our Washington correspondent from the meetings deprives us of abstracts of these valuable papers.

The Anthropological Society.—The Constitution of this society, now in its third year, makes it obligatory upon the President to prepare at the commencement of each year, a summary of the transactions of the organization during the past year. At the close of the first year, the President overlooked this fact, but made ample amends at the commencement of the third year by preparing a pamphlet containing both annual addresses, and copious abstracts of all the papers that had ever been read.

Since our last report, the following papers have been read: "The Savage Mind in the Presence of Civilization," by Prof. Otis T. Mason; "Prehistoric Trephining," by Dr. Robert Fletcher; "Some Superstitions of the Sioux Indians," by Dr. H. Yaddow; "The Chief's Son and the Thunders: An Omaha Myth," by Rev. J. Owen Dorsey.

The design of the first named paper was two-fold: first, to show that the presence of other peoples better furnished and skilled in some respect had always operated as a stimulus in the onward march of civilization; and second to draw attention to the fact that in the treatment of the Indians, Chinese, and Negroes, the phenomena of the past history of civilization were being re-presented. The two latter papers were recitals of exceedingly interesting Indian myths. Dr. Fletcher, who is associated with Dr. Billings in publishing "Index Medicus," having collected all that could be gathered on the subject of prehistoric-trephining, from two years reading, gave an elaborate summary of his investigations.

The Philosophical Society of Washington.—The Spectrophone.—At the 198th meeting of the Philosophical Society of Washington, Prof. Alexander Graham Bell communicated the announcement of his discovery of the Spectrophone, the latest outgrowth of the Photophone.

In a paper read before the American Association for the Advancement of Science, in which he announced the discovery of the photophone, Mr. Bell ventured the prediction that probably all matter would be found to posses sonorous properties of the same nature as those manifested by the discs used in that instrument. More recent investigations in Europe with gases and liquids have fully verified this prediction. Any liquid or gas placed in a test tube and exposed to the action of a beam of light condensed upon it by a lens can be made, by means of an interrupter, to emit musical tones. This has been shown by Prof. Tyndall in his memoir, to the Royal Society, on Radiant Heat. Some substances thus emit feeble sounds, others stronger ones. Iodine vapor, Nitrogen Oxide and Bromine give very loud sounds. It is found that those substances which emit loud sounds are those which absorb heat in a high degree, and among these lamp-black is especially remarkable. It has been questioned whether such sounds are provoked by the luminous rays or by the dark ones. M. Mercadier expressed the belief that the inciting rays are the red and dark ones. This led Mr. Bell, with the assistance of Mr. Sumner Taintor, to experiment with the sonorous properties of Carbon Disulphide, actuated by the light of the Spectrum.

When lamp-black is exposed to the action of the light of the spectrum it is found to give a sonorous response to all of its rays as far as the middle of the violet, and perhaps beyond. The intensity of the sound, however, varies remarkably in different parts of the spectrum. Taking the rays successively from different parts, from the violet towards the red, the sounds begin very feebly and increase in intensity, reaching a maximum in the ultra red. Beyond that point they suddenly cease. The increase of intensity is very gradual, the decrease very sudden.

Other substances have been experimented with, and while exhibiting similar properties, each has a range of its own. Porous and fibrous substances give loud sounds. Thus, common wool or worsted are found to be very sonorous, but the sounds are obtained wholly from the visible parts of the spectrum and have the maximum intensity in the green. In all substances tried success has resulted, but nearly all have a very short range.

In experimenting with more homogeneous substances of simpler constitution, still more definite results are obtained. The rays of the spectrum are passed through sulphuric ether. Outside of the ultra red is a very narrow band which cause sounds while the other parts fail to produce them. Hydrogen peroxide gives sounds at several places wholly within the visible parts of the spectrum, and these places are found to coincide with the positions of the known absorption bands of that substance. The same is found to be true of Nitrogen Oxide and a solution of Ammonia, Sulphate of Copper, and many other substances. The general law deduced is that *sounds are produced in any substance by the rays which it absorbs.*

Thus a kind of spectrum analysis can be obtained through the intermediation of sound. The principal value of the spectrophone, Mr. Bell believes, will be found in the investigation of absorption bands in the ultra red part of the spectrum.

Mr. William B. Taylor inquired whether the sounds observed from the two absorption bands of ammonia, sulphate of copper, were octaves. Mr. Bell replied that this question had not as yet been investigated.

Mr. G. Brown Goode read portions of a paper on the sword-fish and its allies, which paper will be published in full in the next annual report of the U. S. Fish Commission.

ON THE MODERN DEVELOPMENT OF FARADAY'S CONCEPTION OF ELECTRICITY.*

By Professor Helmholtz.

The majority of Faraday's own researches were connected, directly or indirectly, with questions regarding the nature of electricity, and his most important and most renowned discoveries lay in this field. The facts which he has found are universally known. Nevertheless, the fundamental conceptions by which Faraday has been led to these much-admired discoveries have not been received with much consideration. His principal aim was to express in his new conceptions only facts, with the least possible use of hypothetical substances and forces. This was really a progress in general scientific method, destined to purify science from the last remnants of metaphysics. Now that the mathematical interpretations of Faraday's conceptions regarding the nature of electric and magnetic force has been given by Clerk Maxwell, we see how great a degree of exactness and precision was really hidden behind his words, which to his contemporaries appeared so vague or obscure; and it is astonishing in the highest to see what a large number of general theories the methodical deduction of which requires the highest powers of mathematical analysis, he has found by a kind of intuition, with the security of instinct, without the help of a single mathematical formula.

The electrical researches of Faraday, although embracing a great number of apparently minute and disconnected questions, all of which he has treated with the same careful attention and conscientiousness, are really always aiming at two fundamental problems of natural philosophy, the one more regarding the nature of physical forces, or of forces working at a distance; the other, in the same way, regarding chemical forces, or those which act from molecule to molecule, and the relation between these and the first.

The great fundamental problem which Faraday called up anew for discussion was the existence of forces working directly at a distance without any intervening medium. During the last and the beginning of the present century the model after the likeness of which nearly all physical theories had been formed was the force of gravitation acting between the sun, the planets, and their satellites. It is known how, with much caution and even reluctance, Sir Isaac Newton himself proposed his grand hypothesis, which was destined to become the first great and imposing example, illustrating the power of true scientific method.

But then came Oerstedt's discovery of the motions of magnets under the influence of electric currents. The force acting in these phenemena had a new and very singular character. It seemed as if it would drive a single isolated pole of a magnet in a circle around the wire conducting the current, on and on without end, never coming to rest. Faraday saw that a motion of this kind could not be produeed by any force of attraction or repulsion, working from point to point. If the current is able to increase the velocity of the magnet, the magnet must react on the current. So he made the experiment, and discovered induced currents; he traced them out through all the various conditions under which they ought to appear. He concluded that somewhere in a part of the space traversed by magnetic force there exists a peculiar state of tension, and that every change of this tension produces electromotive force. This unknown hypothetical state he called provisionally the electrotonic state, and he was occupied for years and years in finding out what was this electrotonic state. He discovered at first, in 1838, the dielectric polarisation of electric insulators, subject to electric forces. Such bodies show, under the influence of electric forces, phenomena perfectly analogous to those exhibited by soft iron under the influence of the magnetic force. Eleven years later, in 1849, he was able to demonstrate that all ponderable matter is magnetized under the influence of sufficiently intense magnetic force, and at the same time he discovered the phenomena of diamagnetism, which indicated that even space, devoid of all ponderable matter, is magnetizable; and now with quite a wonderful sagacity and intellectual precision Faraday performed in his brain the work of a great mathematician without using a single mathematical formula. He saw with his mind's eye that by these systems of tensions and pressures produced by the dielectric and magnetic polarisation of space which surrounds electrified bodies, magnets or wires conducting electric currents, all the phenomena of electro-static, magnetic, eléctro-magnetic attraction, repulsion, and induction could be explained, without referring at all to forces acting directly at a distance. This was the part of his path where so few could follow him; perhaps a Clerk Maxwell, a second man of the same power and independence of intellect, was necessary to reconstruct in the normal methods of science the great building, the plan of which Faraday had conceived in his mind and attempted to make visible to his contemporaries.

Nevertheless the adherents of direct action at a distance have not yet ceased to search for solutions of the

* The Faraday Lecture, delivered before the Fellows of the Chemical Society in the Theatre of the Royal Institution, on Tuesday, April 5th, 1881, by Professor Helmholtz. Abstract revised by the author.

electro-magnetic problem. The present development of science, however, shows, as I think, a state of things very favorable to the hope that Faraday's fundamental conceptions may in the immediate future receive general assent. His theory, indeed, is the only existing one which is at the same time in perfect harmony with the facts observed, and which at least does not lead into any contradiction against the general axioms of dynamics.

It is not at all necessary to accept any definite opinion about the ultimate nature of the agent which we call electricity.

Faraday himself avoided as much as he could giving any affirmative assertion regarding this problem, although he did not conceal his disinclination to believe in the existence of two opposite electric fluids.

For our own discussion of the electro-chemical phenomena, to which we shall turn now, I beg permission to use the language of the old dualistic theory, because we shall have to speak principally on relations of quantity.

I now turn to the second fundamental problem aimed at by Faraday, the connection between electric and chemical force. Already, before Faraday went to work, an elaborate electro-chemical theory had been established by the renowned Swedish chemist, Berzelius, which formed the connecting-link of the great work of his life, the systematisation of the chemical knowledge of his time. His starting point was the series into which Volta had arranged the metals according to the electric tension which they exhibit after contact with each other, a fundamental point which Faraday's experiment contradicted with the supposition that the quantity of electricity collected in each atom was dependent on their mutual electro-chemical differences, which he considered as the cause of their apparently greater chemical affinity. But although the fundamental conceptions of Berzelius's theory have been forsaken, chemists have not ceased to speak of positive and negative constituents of a compound body. Nobody can overlook that such a contrast of qualities, as was expressed in Berzelius's theory, really exists, well developed at the extremities, less evident in the middle terms of the series, playing an important part in all chemical actions, although often subordinated to other influences.

When Faraday began to study the phenomena of decomposition by the galvanic current, which of course were considered by Berzelius as one of the firmest supports of his theory, he put a very simple question ; the first question, indeed, which every chemist speculating about electrolysis ought to have answered. He asked, What is the quantity of electrolytic decomposition if the same quantity of electricity is sent through several electrolytic cells? By this investigation he discovered that most important law, generally known under his name, but called by him the law of definite electrolytic action.

Faraday concluded from his experiments that a definite quantity of electricity cannot pass a voltametric cell containing acidulated water between electrodes of platinum without setting free at the negative electrode a corresponding definite amount of hydrogen, and at the positive electrode the equivalent quantity of oxygen, one atom of oxygen for every pair of atoms of hydrogen. If instead of hydrogen any other element capable of substituting hydrogen is separated from the electrolyte, this is done also in a quantity exactly equivalent to the quantity of hydrogen which would have been evolved by the same electric current.

Since that time our experimental methods and our knowledge of the laws of electrical phenomena have made enormous progress, and a great many obstacles have now been removed which entangled every one of Faraday's steps, and obliged him to fight with the confused ideas and ill-applied theoretical conceptions of some of his contemporaries. We need not hesitate to say that the more experimental methods were refined, the more the exactness and generality of Faraday's law was confirmed.

In the beginning Berzelius and the adherents of Volta's original theory of galvanism, based on the effects of metallic contact, raised many objections against Faraday's law. By the combination of Nobili's astatic pairs of magnetic needles with Schweigger's multiplicator, a coil of copper wire with numerous circumvolutions, galvanometers became so delicate that the electro-chemical equivalent of the smaller currents they indicated was imperceptible for all chemical methods. With the newest galvanometers you can very well observe currents which would want to last a century before decomposing one milligram of water, the smallest quantity which is usually weighed on chemical balances. You see that if such a current lasts only some seconds or some minutes, there is not the slightest hope to discover its products of decomposition by chemical analysis. And even if it should last a long time the feeble quantities of hydrogen collected at the negative electrode can vanish, because they combine with the traces of atmospheric oxygen absorbed by the liquid. Under such conditions a feeble current may continue as long as you like without producing any visible trace of electrolysis, even not of galvanic polarisation, the appearance of which can be used as an indication of previous electrolysis. Galvanic polarisation, as you know, is an altered state of the metallic plates which have been used as electrodes during the decomposition of an electrolyte. Polarised electrodes, when connected by a galvanometer, give a current which they did not give before being polarised. By this current the plates are discharged again and returned to their original state of equality.

This depolarising current is indeed a most delicate means of discovering previous decomposition. I have really ascertained that under favorable conditions one can observe the polarisation produced during some seconds by a current which decomposes one milligram of water in a century.

Products of decomposition cannot appear at the electrodes without motions of the constituent molecules of the electrolyte throughout the whole length of the liquid. This subject has been studied very carefully, and for a great number of liquids, by Prof. Hittorff, of Münster, and Prof. G. Wiedemann, of Leipsic.

Prof. F. Kohlrausch, of Würzburg, has brought to light the very important fact that in diluted solutions of salts, including hydrates of acids and hydrates of caustic alkalies, every atom under the influence of currents of the same density moves on with its own peculiar velocity, independently of other atoms moving at the same time in the same or in opposite directions. The total amount of chemical motion in every section of the fluid is represented by the sum of the equivalents of the cation gone forwards and of the anion gone backwards, in the same way as in the dualistic theory of electricity, and the total amount of electricity flowing through a section of the conductor corresponds to the sum of positive electricity going forwards and negative electricity going backwards.

This established, Faraday's law tells us that through each section of an electrolytic conductor we have always equivalent electrical and chemical motion. The same definite quantity of either positive or negative electricity moves always with each univalent ion, or with every unit of affinity of a multivalent ion, and accompanies it during all its motions through the interior of the electrolytic fluid. This we may call the electric charge of the atom.

Now the most startling result, perhaps, of Faraday's law is this : If we accept the hypothesis that the elementary substances are composed of atoms we cannot avoid concluding that electricity also, positive as well as negative, is divided into definite elementary portions, which behave like atoms of electricity. As long as it moves about on the electrolytic liquid each atom remains united

with its electric equivalent or equivalents. At the surface of the electrodes decomposition can take place if there is sufficient electromotive power, and then the atoms give off their electric charges and become electrically neutral.

Now arises the question, Are all these relations between electricity and chemical combination limited to that class of bodies which we know as electrolytes? In order to produce a current of sufficient strength to collect enough of the products of decomposition without producing too much heat in the electrolyte, the substance which we try to decompose ought not to have too much resistance against the current. But this resistance may be very great, and the motion of the ions may be very slow, so slow indeed that we should need to allow it to go on for hundreds of years before we should be able to collect even traces of the products of decomposition; nevertheless all the essential attributes of the process of electrolysis could subsist. If you connect an electrified conductor with one of the electrodes of a cell filled with oil of turpentine, the other with the earth, you will find that the electricity of the conductor is discharged unmistakably more rapidly through the oil of turpentine than if you take it away and fill the cell only with air.

Also in this case we may observe polarisation of the electrodes as a symptom of previous electrolysis. Another sign of electrolytic conduction is that liquids brought between two different metals produce an electromotive force. This is never done by metals of equal temperature, or other conductors which, like metals, let electricity pass without being decomposed.

The same effect is also observed even with a great many rigid bodies, although we have very few solid bodies which allow us to observe this electrolytic conduction with the galvanometer, and even these only to temperatures near to their melting-point. It is nearly impossible to shelter the quadrants of a delicate electrometer against being charged by the insulating bodies by which they are supported.

In all the cases which I have quoted one might suspect that traces of humidity absorbed by the substance or adhering to their surface were the electrolytes. I show you therefore this little Daniell's cell, in which the porous septum has been substituted by a thin stratum of glass. Externally all is symmetrical at both poles; there is nothing in contact with the air but a closed surface of glass, through which two wires of platinum penetrate. The whole charges the electrometer exactly like a Daniell's cell of very great resistance, and this it would not do if the septum of glass did not behave like an electrolyte. All these facts show that electrolytic conduction is not at all limited to solutions of acids or salts.

Hitherto we have studied the motions of ponderable matter as well as of electricity, going on in an electrolyte. Let us study now the forces which are able to produce these motions. It has always appeared somewhat startling to everybody who knows the mighty power of chemical forces, the enormous quantity of heat and of mechanical work which they are able to produce, and who compares with it the exceedingly small electric attraction which the poles of a battery of two Daniell's cells show. Nevertheless this little apparatus is able to decompose water.

The quantity of electricity which can be conveyed by a very small quantity of hydrogen, when measured by its electrostatic forces, is exceedingly great. Faraday saw this, and has endeavored in various ways to give at least an approximate determination. The most powerful batteries of Leyden jars, discharged through a voltameter, give scarcely any visible traces of gases. At present we can give definite numbers. The result is that the electricity of 1 m.grm. of water, separated and communicated to two balls, 1 kilometre distant, would produce an attraction between them, equal to the weight of 25,000 kilos.

The total force exerted by the attraction of an electrified body upon another charged with opposite electricity is always proportional to the quantity of electricity contained in the attracting as on the attracted body, and therefore even the feeble electric tension of two Daniell's elements, acting through an electrolytic cell upon the enormous quantities of electricity with which the constituent ions of water are charged, is mighty enough to separate these elements and to keep them separated.

We now turn to investigate what motions of the ponderable molecules require the action of these forces. Let us begin with the case where the conducting liquid is surrounded everywhere by insulated bodies. Then no electricity can enter, none can go out through its surface, but positive electricity can be driven to one side, negative to the other, by the attracting and repelling forces of external electrified bodies. This process going on as well in every metallic conductor is called "electrostatic induction." Liquid conductors behave quite like metals under these conditions. Prof. Wüllner has proved that even our best insulators, exposed to electric forces for a long time, are charged at last quite in the same way as metals would be charged in an instant. There can be no doubt that even electromotive forces going down to less than 1-100 Daniell produce perfect electrical equilibrium in the interior of an electrolytic liquid.

Another somewhat modified instance of the same effects is afforded by a voltametric cell containing two electrodes of platinum, which are connected with a Daniell's cell, the electromotive force of which is insufficient to decompose the electrolyte. Under this condition the ions carried to the electrodes cannot give off their electric charges. The whole apparatus behaves, as was first accentuated by Sir W. Thomson, like a condenser of enormous capacity.

Observing the polarizing and depolarizing currents in a cell containing two electrodes of platinum, hermetically sealed and freed of all air, we can observe these phenomena with the most feeble electromotive forces of 1-1000 Daniell, and I found that down to this limit the capacity of the platinum surfaces proved to be constant. By taking greater surfaces of platinum I suppose it will be possible to reach a limit much lower than that. If any chemical force existed besides that of the electrical charges which could bind all the pairs of opposite ions together, and require any amount of work to be vanquished, an inferior limit to the electromotive forces ought to exist, which forces are able to attract the atoms to the electrodes and to charge these as condensers. No phenomenon indicating such a limit has as yet been discovered, and we must conclude, therefore, that no other force resists the motions of the ions through the interior of the liquid than the mutual attractions of their electric charges.

On the contrary, as soon as an ion is to be separated from its electrical charge we find that the electrical forces of the battery meet with a powerful resistance, the overpowering of which requires a good deal of work to be done. Usually the ions, losing their electric charges, are separated at the same time from the liquid; some of them are evolved as gases, others are deposited as rigid strata on the surface of the electrodes, like galvanoplastic copper. But the union of two constituents having powerful affinity to form a chemical compound, as you know very well, produces always a great amount of heat, and heat is equivalent to work. On the contrary, decomposition of the compound substances requires work, because it restores the energy of the chemical forces, which has been spent by the act of combination.

Metals uniting with oxygen or halogens produce heat in the same way, some of them, like potassium, sodium, zinc, even more heat than an equivalent quantity of hydrogen; less oxidisible metals, like copper, silver, platinum, less. We find, therefore, that heat is generated when zinc drives copper out of its combination with the

compound halogen of sulphuric acid, as is the case in a Daniell's cell.

If a galvanic current passes through any conductor, a metallic wire, or an electrolytic fluid, it evolves heat. Mr. Prescott Joule was the first who proved experimentally that if no other work is done by the current the total amount of heat evolved in a galvanic circuit during a certain time is exactly equal to that which ought to have been generated by the chemical actions which have been performed during that time. But this heat is not evolved at the surface of the electrodes, where these chemical actions take place, but it is evolved in all the parts of the circuit, proportionally to the galvanic resistance of every part. From this it is evident that the heat evolved is an immediate effect, not of the chemical action, but of the galvanic current, and that the chemical work of the battery has been spent in producing only the electric action.

If we apply Faraday's law, a definite amount of electricity passing through the circuit corresponds to a definite amount of chemical decomposition going on in every electrolytic cell of the same circuit. According to the theory of electricity the work done by such a definite quantity of electricity which passes, producing a current, is proportionate to the electromotive force acting between both ends of the conductor. You see, therefore, that the electromotive force of a galvanic circuit must be, and is, indeed, proportionate to the heat generated by the sum of all the chemical actions going on in all the electrolytic cells during the passage of the same quantity of electricity. In cells of the galvanic battery chemical forces are brought into action able to produce work; in cells in which decomposition is occurring work must be done against opposing chemical forces; the rest of the work done appears as heat evolved by the current, as far as it is not used up to produce motions of magnets or other equivalents of work.

Hitherto we have supposed that the ion with its electric charge is separated from the fluid. But the ponderable atoms can give off their electricity to the electrode, and remain in the liquid, being now electrically neutral. This makes almost no difference in the value of the electromotive force. For instance, if chlorine is separated at the anode, it will remain at first absorbed by the liquid; if the solution becomes saturated, or if we make a vacuum over the liquid, the gas will rise in bubbles. The electromotive power remains unaltered. The same may be observed with all the other gases. You see in this case that the change of electrically negative chlorine into neutral chlorine is the process which requires so great an amount of work, even if the ponderable matter of the atoms remains where it was.

The more the surface of the positive electrode is covered with negative atoms of the anion, and the negative with the positive ones of the cation, the more the attracting force of the electrodes exerted upon the ions of the liquid is diminished by this second stratum of opposite electricity covering them. On the contrary, the force with which the positive electricity of an atom of hydrogen is attracted towards the negatively charged metal increases in proportion as more negative electricity collects before it on the metal, and the more negative electricity collects behind it in the fluid.

Such is the mechanism by which electric force is concentrated and increased in its intensity to such a degree that it becomes able to overpower the mightiest chemical affinities we know of. If this can be done by a polarized surface, acting like a condenser, charged by a very moderate electromotive force, can the attractions between the enormous electric charges of anions and cations play an unimportant and indifferent part in chemical affinity?

You see, therefore, if we use the language of the dualistic theory and treat positive and negative electricities as two substances, the phenomena are the same as if equivalents of positive and negative electricity were attracted by different atoms, and perhaps also by the different values of affinity belonging to the same atom with different force. Potassium, sodium, zinc, must have strong attraction to a positive charge; oxygen, chlorine, bromine to a negative charge.

Faraday very often recurs to this to express his conviction that the forces termed chemical affinity and electricity are one and the same. I have endeavored to give you a survey of the facts in their mutual connection, avoiding, as far as possible, introducing other hypotheses, except the atomic theory of modern chemistry. I think the facts leave no doubt that the very mightiest among the chemical forces are of electric origin. The atoms cling to their electric charges and the opposite electric charges cling to the atoms. But I don't suppose that other molecular forces are excluded, working directly from atom to atom. Several of our leading chemists have begun lately to distinguish two classes of compounds, molecular aggregates and typical compounds. The latter are united by atomic affinities, the former not. Electrolytes belong to the latter class.

If we conclude from the facts that every unit of affinity of every atom is charged always with one equivalent either of positive or of negative electricity, they can form compounds, being electrically neutral, only if every unit charged positively unites under the influence of a mighty electric attraction with another unit charged negatively. You see that this ought to produce compounds in which every unit of affinity of every atom is connected with one and only with one other unit of another atom. This is, as you will see immediately, indeed, the modern chemical theory of quantivalence, comprising all the saturated compounds. The fact that even elementary substances, with few exceptions, have molecules composed of two atoms, makes it probable that even in these cases electric neutralization is produced by the combination of two atoms, each charged with its electric equivalent, not by neutralization of every single unit of affinity.

But I abstain from entering into mere specialties, as for instance, the question of unsaturated compounds; perhaps I have gone already too far. I would not have dared to do it if I did not feel myself sheltered by the authority of that great man who was guided by a never-erring instinct of truth. I thought that the best I could do for his memory was to recall to the minds of the men, by the energy and intelligence of whom chemistry has undergone its modern astonishing development, what important treasures of knowledge lie still hidden in the works of that wonderful genius. I am not sufficiently acquainted with chemistry to be confident that I have given the right interpretation, that interpretation which Faraday himself would have given perhaps, if he had known the law of chemical quantivalence, if he had had the experimental means of ascertaining how large the extent, how unexceptional the accuracy of his law really is; and if he had known the precise formulation of the law of energy applied to chemical work, and of the laws which determine the distribution of electric forces in space as well as in ponderable bodies transmitting electric current or forming condensers. I shall consider my work of to-day well rewarded if I have succeeded in kindling anew the interest of chemists for the electro-chemical part of their science.

MANUFACTURE OF SODA FROM SULPHATE.—Salt-cake is produced in quantity in California in the manufacture of nitric acid. As coal and lime-stone are dear in California, Le Blanc's process is not economical. The author therefore proposes to mix a solution of salt cake with calcium sulphite and pass in sulphurous acid. Soluble calcium bisulphite is formed, and by decomposition calcium sulphate and sodium bisulphite. The two salts are separated by filtration, and the sodium bisulphite is treated with milk of lime. The result is a solution of caustic soda, retaining a certain quantity of sodium sulphite and sulphate, which is evaporated down in the usual manner, and calcium sulphite, which is used again in the process.—J. PUTZKOW,

THE YELLOWSTONE NATIONAL PARK.

ANNUAL REPORT OF THE SUPERINTENDENT OF THE YELLOWSTONE NATIONAL PARK—to the Secretary of the Interior, for the year 1880.—Washington, 1881.

The chief feature of interest found in this report is a description of what is termed the Hoodoo Region, which is a terribly broken and eroded portion of the head branches of the East Fork of the Yellowstone and the Passamaria or Stinking Water Fork of the Big Horn, and which until this occasion had never been visited by tourists or government explorers; all previous information having been derived from a small party of prospecting miners, two of whom were killed by the Indians.

Mr. P. W. Norris, the Superintendent of the Park, having arrived on the ground with his party, some made sketches of the many weird wonders of erosion, copies of which may be found on another page of this issue, and Mr. Norris with an attendant took the elevations of the adjacent peaks, including Hoodoo Mountain. The latter was found to be 10,700 feet high (anneroid-barometer measurement).

This mountain is about a mile in length, and must present a most extraordinary appearance, and while probably itself not a crater, it is evidently of volcanic origin, and was eroded in its present form. Its southern face is still changing, here extending from 500 to 1500 feet below the summit; the frosts and storms of untold ages in an Alpine climate have worn about a dozen labyrinths of countless deep, narrow, tortuous channels amid the long, slender, tottering pillars, shafts and spires of conglomerate breccia and other remaining volcanic rocks. In shape they are described as being unlike any elsewhere known, being a cross between the usual spire and steeple form, and the slender-based, and flat, tottering, table-topped sandstone monuments, near the Garden of the Gods, in Colorado. And while lacking the symmetry and beauty of these, surpass both in wild weird fascination. Here the sharp-cornered fragments of rocks of nearly every size, form and formation, and shade of coloring, by a peculiar volcanic cement attached sideways, endwise, and upon the tops, sides, and apparently unsupported upon each other, represent every form, garb and posture of gigantic human beings, as well as of birds, beasts and reptiles. In fact nearly every form, animate or inanimate, real or chimerical ever actually seen or conjured by the imagination may here be observed. With this description and the illustrations we have given on page 187, some idea may be formed of the wild unearthly appearance of these eroded Hoodoos of the Goblin Land. These monuments are from 50 to 300 feet in height, with narrow tortuous passages between them, with sometimes tunnels, where the Big Horn sheep hide in safety; while the ceaseless but ever changing moans of the wild winds seem to chant fitting requiems to these gnome-like monuments of the legendary Indian Gods.

We have not sufficient space to allow us even to briefly follow Superintendent Norris in his very interesting description of the many wonders of this extraordinary region—the Yellowstone Lake, Geysers, cold, hot and medicinal springs, pulsating Geysers, terrace building springs, fossil forests, natural bridges, gold and silver mines, and many objects of scientific interest. Among the animals still to be found in the Yellowstone Park, mention is made of the bison, or mountain buffalo, which differs considerably from the bison of the plains; also the moose, elk, white tailed deer, black tailed deer, antelope, big horn sheep, bears, mountain lion or cougar, wolves, foxes, skunks, badgers, rock dog, porcupine, rabbits, rats, mice, moles, squirrels, chipmunks, beavers, otters, etc., etc.

We note the presence in trout, found in the cold water tributaries, of a "worm" named by Dr. Leidy "*Dibothrium cordiceps*." They are described "as long, slender, white worms, found in the intestines and flesh of the countless large and beautiful trout of the Yellowstone Lake, named by Professor Cope, *Salmo pleuriticus*." They are said to be entirely different to the worms found in European trout. The Superintendent does not appear to have succeeded in tracing the cause of this parasite, but states that they are only met with in fish found in the Yellowstone Lake. Here the trout exist in great numbers in water bubbling with hot gases; and the angler, without changing his position, or removing the fish from the hook, can rapidly boil them in seething pools.

This National Park of the United States was visited by over 2000 tourists during the season previous to this report, all of whom returned in safety, although much inconvenience was experienced from the condition of the roads. An appropriation is now annually made for the improvement of the Park; and no one reading this report can fail to come to the conclusion that Mr. P. W. Norris is a gentleman highly qualified for the position of Superintendent, and brings an enthusiastic devotion to bear on his arduous duties in developing this "peerless wonder-land of earth."

Statement showing the *mean temperature* at BOSTON, MASS., for *each month* and *year* from *January*, 1871, to *December*, 1880, inclusive, as recorded at the *station of observation* of the *Signal Service, U. S. Army*, at that place.

[Compiled from the records on file at the office of the Chief Signal Officer, U. S. A., Washington, D. C.]

YEAR.	MEAN TEMPERATURE.

HOODOOS OR REMNANTS OF EROSION IN THE GOBLIN LABYRINTHS.

YELLOW STONE NATIONAL PARK.

NOTE ON THE SENSORY TRACT OF THE BRAIN.

By Edward C. Spitzka, M. D., New York City.

It is well known that Meynert ([1]) and those who followed that distinguished anatomist, believed that the tract through which the conscious sensory impressions reach the cortex, extends from the columns of Goll and Burdach, of the cord and lower oblongata, through the so-called superior or sensory decussation, to the anterior pyramids; that thence the tract runs with the anterior pyramids in their outermost third through the pons and pes pedunculi, courses between the thalamus and lenticular nucleus in the posterior third of the internal capsule, and arching back, terminates in the cortex of the occipital lobe. Flechsig showed that what Meynert interpreted as the sensory pyramidal decussation, has no connection with the anterior pyramids, but, on the contrary, enters the lemniscus layer, or interolivary strand, whose relations to the corpora quadrigemina had been explained by Meynert, although he was befogged as to its lower relations, owing to the aforesaid confounding with the anterior pyramids proper.

Now, Flechsig ([2]) distinctly states in his work that the explanation he has been able to furnish of the real nature of the superior decussation, demonstrates the non-exist ence of a direct tract from that decussation to the cortex.

The true tract has, however, been known to exist, although the relations have not been properly interpreted. The lemniscus layer is not only a detachment from the corpora quadrigemina, but also distinctly incorporates a peculiar bundle, described by Henle as a fasciculus, from the pes to the tegmentum([3]). This tract continues, in at least a part of the fibres, from the columns of Goll and Burdach to the pes pedunculi and thence, no doubt, to the cortex of the brain. The circuit for the conscious sensory impressions transmitted by the cord, and proposed by Meynert, therefore becomes re-established, with a modification, namely, that the sensory tract does not run through the pyramids and pons, but immediately above them, and after entering the *pes pedunculi* probably takes the course claimed by Meynert.

That there is a close relation between the pyramidal tracts and the by-track from the superior decussation to the *pes pedunculi*, is proven by an interesting observation which I have been able to make on the elephant's brain. In this animal([4]) the entire pyramidal tract takes the course of the by-track, that is, there are no vertical fibres in the pons. The crus is continued bodily above the latter (which is composed exclusively of transverse fibres) to take the usual course on the ventral and medial aspect of the olivary nucleus.

This fact strengthens the proposition of Meynert, that there intervenes a third projection series between that of the tegmentum and that of the pes pedunculi, for which he proposes the name of the *stratum intermedium* ([5]). In man, I believe this stratum intermedium to be the main tract for the conveyance of conscious sensory impressions from the general sensory periphery, while in other animals, at least in the elephant, it is at the same time the voluntary motor tract.

That the sensory fibres occupy the most posterior portion of the internal capsule, while they compose the most dorsal in the pes pedunculi, shows that the fibres of the latter must pursue a spirally twisted course before entering the brain. Such an arrangement seems to be indicated, indeed, in the outer contours of the crus. In an early human embryo, of about the third month, I find a well marked columnar elevation running from the outer part of the crus through the pons, where it touches its fellow of the opposite side, and then passes between the olives([6]). This I regard as the embryonically distinct stratum intermedium.

ASTRONOMIAL MEMORANDA.

A small pamphlet containing notes, corrections, etc., to the "Handbook of Double Stars," has been recently prepared by Messrs. Crossly, Gledhill and Wilson. In the introduction, the editors say: "The corrections have been thrown into two classes: the first contains those which from their importance demand immediate attention in order to save waste of time. These the reader is requested to insert at once. In the second list will be found a large number of corrections which may be entered as the stars are observed or read.

A very copious set of additional notes has also been drawn up, embodying, so far as we know them, the most recent and improved orbits, measures and discoveries.

It seems probable that the asteroid, No. 220, discovered by Palisa on the 23d of March, is identical with No. 139, Juewa. Juewa was discovered by the late Prof. Watson while engaged upon one of the transit of Venus parties in 1874 at Pekin. The asteroid was observed by Rümker at Hamburg, on November 8th of the same year, but since that date it has not been seen.

Nature for March 17, contains the following note upon the largest refractor in the world. "A very interesting scientific work, the most important of its kind yet attempted in the kingdom, has just been completed. It is the great refracting telescope, constructed by Mr. Grubb, of Rathmines, Dublin, for the Austro-Hungarian Government, and it is to be placed in the Observatory at Vienna. A commission appointed by the Government to examine the work, transmitted yesterday to the Austro-Hungarian Embassy, in London, a report expressing their full approval of the manner in which the task has been completed. It is a matter of no little pride to Ireland that she has produced the largest refracting as well as the largest reflecting telescope in the world." The object glass of this instrument is 27 inches in diameter or 1 inch larger than that of the Washington Refractor made by Clark.

W. C. W.

Washington, D. C., *April* 21, 1881.

INTRA-MERCURIAL PLANETS.

In "Science" of February 26, appeared an article on the above subject by "W. C. W.," which I have read with considerable personal interest, wherein we are led to infer, from purely negative testimony alone, that no such objects were seen during the total eclipse of Aug. 29, 1878, either by the late Prof. Watson or myself. Unfortunately, Prof. Watson's tongue and pen are now silent, and no one exists to defend his observations. What he has written on the subject the astronomical world is familiar with. It is about my own I wish to speak, and in defending them against the negative testimony which your correspondent brings, I hope to be able to convince the reader that because the observers whom he cites saw no planets, it is very far from proving their non-existence.

If the reader will refer to the article itself, he will find delineated on a chart the ground swept over by six observers, but he fails to tell us how short a time was devoted to a search west of the sun, and especially in the immediate region of the two objects seen by me, and near which one of Watson's objects was, viz., near θ Cancri. As not one in a thousand of your readers will have the privilege of reading the reports of those six observers, just published by the Naval Observatory, and, are therefore incapable of forming a correct conclusion on the subject, I have thought it advisable to quote what they really say, and, to remark, that when negative testimony is arrayed against positive, it is very important that its weight, if it has any, be carefully considered.

First, let the fact be stated, that during the total phase of the eclipse which lasted but 162 seconds, two experienced observers, with telescopes in every way well adapted for the work, state with positiveness that each saw two objects not down on any star chart, and, that they were not there when the sun had sufficiently withdrawn to allow the locality to be re-observed. On the other hand, three observers who searched west of the sun, one in a cloudy sky, and two of the others poorly equipped, and, devoting but a few seconds to the search, saw nothing, not even θ Cancri, a star of the fifth magnitude, near where one of Watson's and both of my objects were seen. The weakness of this negative testimony will be apparent from a few extracts from their reports.

Mr. Wheeler (telescope 5 inch, power 100) says, he observed the second and third contacts (beginning and end of totality), also the Corona on both sides of the sun, saw with the naked eye Venus, Mercury and Regulus, observed carefully the several prominences, etc., and then says, "An unsatisfactory attempt was made to sweep for Vulcan. The time given to it was limited, as I was expected to observe all the contacts, and time was consumed in recording the second, and again in bringing the telescope into position for observing the third contact." Now when it is considered that he undoubtedly occupied several seconds in looking at the grand sight with the naked eye, and, that the power used was altogether too high, and of course, the field very small, the time devoted to the search for Vulcan could have been but a few seconds. Is it therefore surprising that Mr. Wheeler saw nothing of the objects seen by me? Only those familiar with the use of telescopes know how perplexingly difficult it is to bring a well-known object in the field of a telescope, using a power of 100.

Mr. Bowman (telescope 3 inch, power 30) says he searched *north* and west of the sun (my objects, also Watson's, were southwest), and that some time was lost (during totality) in exchanging the diagonal tube for the straight one, swept to the westward 5° or 6° in the declination of the sun, and then returning, shifted the declination just far enough *north* to clear the Corona and swept to the westward again, then returned to the R. A. of the sun and shifted to the proper declination just in time to observe the third contact. When it is considered how much precious time was lost in observing and recording in his note-book the time of second contact, changing tubes, and probably observing the eclipse for several seconds with his naked eye, which he could hardly refrain from doing, is it at all wonderful that Mr. Bowman saw nothing of my objects or Watson's either?

Prof. Todd (telescope 4 inch, power 20) says, "I searched 15° each side of the sun, but the sky was *cloudy*, so much so that I was unable to see Delta Cancri," (a 4th mag. star). He does not say how much time he spent searching west of the sun. It certainly could have been but a moment, and, in the region where my objects were, but a few seconds. He, too, observed the second contact, also the Corona, saw Mercury, Venus, Mars, and Procyon. Again I ask is it at all surprising that Prof. Todd saw nothing of the objects seen by me?

Prof. Pritchett (telescope 3½ inch, power 90) says he first observed the grand scene with a naked eye, then swept along the ecliptic several degrees *each* side of the sun, observed all the phenomena of the eclipse, the second contact, Corona, the prominences, and the question arises how many seconds he searched with a very small field west of the sun for the "Ghost of Vulcan," as he facetiously calls it. Still again I ask is it at all wonderful that Prof. Pritchett saw nothing of the objects seen by me? Would it not, in fact, have been very surprising had he seen them at all?

Your correspondent has given in his diagram the outlines of the regions swept over by the above observers, saying: "The place of one of Watson's stars was covered by Wheeler, Bowman and Pritchett, and the place of Swift's two stars was examined by Bowman and Wheeler, and that one of the stars appears in the corner of Pritchett's sweep." Now all this is calculated to convey a wrong impression, for it is not likely that either of them knew within from 1° to 3° the exact boundaries of their hastily-made sweeps; neither do I pretend to be exact about the location of the stars I saw, although I made three estimates of their deviation and distance from the sun, by sighting along the outside of the telescope tube.

They are wrongly placed in the diagram. They were nearer where Theta is, and probably somewhat west of it, which would place it outside of the sweeps of all the observers. I should strongly suspect that one of them was θ, were it not that Watson, who says he saw that star, says nothing about another equally bright some 7′ from it, both ranging with the sun's centre.

Neither in his published statements, or letters to me, does he allude to this vital point. It was as impossible for him to have seen one and not the other, as for one to see Epsilon 4 Lyræ, without, at the same time, seeing Epsilon 5.

Again, he says, as far as relative position is concerned, my objects resemble closely d^2 Cancri, and B. A. C. 2810, on the *east* side of the sun. I hope he does not mean to be understood as inferring that it was on the east, instead of the west, of the sun I was searching.

Finally, he says, the existence of an intra-mercurial planet is not yet admitted by the majority of astronomers. This may be true, but I hope their opinion is based on stronger evidence than that adduced by "W. C. W."

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

DISCREPANCIES IN RECENT SCIENCE.

To the Editor of SCIENCE :—

The article on "Discrepancies in Recent Science" in a late number of this journal demands some attention, not because the Nebula Theory is seriously threatened by it, but because it properly calls attentions to some physical inferences that have been drawn from other phenomena and applied to the Nebula Theory, especially in the domain of heat. It is assumed by the writers quoted in that article, that *luminousness implies high temperature* and also that the rarity of the gaseous material of the nebula is the immediate result of the high temperature of the constituent atoms. Neither of these assumptions is correct. The trouble comes chiefly from the writer's failure to make the proper distinction between *energy* and *heat*, and I apprehend, also, in the failure to see clearly what the nature of heat is. Most of the books treat of this in a very loose way, and most of the statements on the subject by Mr. Charles Morris are wrong. How far wrong may be seen by comparing his statements with the following quotation from "The Mechanical Theory of Heat," by Clausius, Chap. 1st, Sec. X, p. 24: "*All heat existing in a body is appreciable by the touch and by the thermometer; the heat which disappears under the above changes of condition (fusion and vaporization) exist no longer as heat, but has been converted into work, and the heat which makes its appearance under the opposite changes (solidification and condensation) does not come from any concealed source, but is newly produced by work done on the body.*" We have all along been familiar with the conception of *heat as a mode of motion*, but not with the character of the motion except as "a brisk agitation of the molecules" or "a rapid vibration of the atoms;" but there are two kinds of vibratory motions possible to atoms, one of the character of pendulous motion or a

change of position in space of the centre of gravity of the atom, and the other the change of form of the atom itself; the first of these is known as free path motion, and the second as heat. The evidence for this may be briefly given.

First—It is certain that a heated body loses its heat by radiation, that is, it imparts its motion to the ether which transmits it in every direction as undulations having certain wave lengths and amplitudes. Second—It is certain that the energy of such undulations depends upon the amplitude of such undulations, and if the amplitude of the undulation was measured by the free path of the atom, then the radiant energy of the atom would vary as its free path, or in other words the rarer a gas is the greater its radiant energy. Now when the spectrum of a gas, say hydrogen, is examined, it is seen to be composed of lines having definite wave lengths, and wave length is dependent solely upon the rate of vibration. If this rate depended upon the number of impacts per second of the atoms or molecules of a gas, then these atoms would need to be always at exactly the same distance apart and the velocity of free path motion invariable, which conditions are physically impossible among free atoms, otherwise the spectrum we should obtain would be a continuous spectrum such as solid incandescent bodies give. But the spectrum of hydrogen for a given temperature is the same whether the gas be at ordinary pressure or very rare. This necessitates the conclusion that the heated atom which is thus radiating energy is vibrating quite independent of its position in space or of its free path motion, and the energy embodied in such vibratory motion is often spoken of as *internal energy*. When a swiftly moving bullet strikes a target, both bullet and target are heated and oftentimes a flash of light may be seen at the instant of impact. The free path motion has been changed into atomic vibrations, which at the first instant had a period capable of giving the sensation of light, but if the bullet be picked up at once it may not be uncomfortably hot. Now imagine two atoms in space urged by gravitation towards each other until they strike each other; each will be set vibrating, that is they will both be heated by impact, and until they were thus made to vibrate they would have no temperature at all; their energy would be represented by their free path motion; the greater their distance apart, when they began to approach, the greater would be their velocity at impact, and the period of vibration of each after impact would depend upon the character of the atoms themselves. One might have such a period as to give out undulations that might affect the eyes and we would say it was luminous while the other one might not, luminosity being dependent upon the rate of vibration, not upon the energy of vibration or the amplitude.

There are many phenomena, that are familiar enough, which show that luminosity does not depend upon high temperature. The decaying stump that shines at night, has a temperature not appreciably higher than surrounding objects; the swift moving molecules in a Crookes tube, that spend their energy upon the walls of the tube, cause the latter to glow, and the molecules themselves shine as they move in their long, free paths, but the tube is not uncomfortably hot, much less *very hot*. It is true that by increasing the energy of the moving atoms, the tube may be made red hot, but the point here is, that this is not essential for luminosity.

If then, in the process of universe building, we start with dissociated atoms, without any temperature,—at absolute zero, and let gravitation alone act among them, the first motions will be free path motions, and there will be no such thing as heat until atomic impact has begun; the energy that was at first represented solely by gravitation will now be partly changed into heat and radiation proper will begin, and the actual loss of energy to the involved atom will be greater than what would be due solely to gravitative approach; there might be luminousness with very little temperature, and one might speak of it as "fire mist," and as "glowing vapor," and yet not threaten the "Law of Interaction of Forces." Neither does the Nebula Theory fall, if originally matter was not hot, but cold.

DISCREPANCIES IN RECENT SCIENCE.

To the Editor of "SCIENCE:"

In his communication to your excellent journal (Vol. II., p. 142), Mr. Larkin has very correctly stated the discrepancy which is contained in the designation "fire-mist," as applied to the initiatory stage of nebular cosmogeny, the "Chaos" of Laplace—*sit venia verbo!* If the Nebular Hypothesis is a true representation of the history of our solar system (or all solar and other systems, for that matter) then, certainly, *heat* could have been present only after motion, and very lively motion at that, had been going on for quite a number of—well, let us say, billions of years, or pretty nearly that.

As soon as motion, *i. e.*, aggregation (and rotation) had begun, then, by the impact of the more distant portions of matter on those nearer the centre of the solar nucleus, heat was produced equivalent to the motion thus arrested. The primordial "Chaos," therefore, was cold and dark, if it ever did exist at all.

Mr. Larkin, consequently, is correct: There *is* a discrepancy!

Not so, Mr. Morris, whose objection is stated, *in nuce*, by himself (Vol. II., No. 41) in these words:

"Temperature and heat are very different things."

"It is one thing to contain heat and another thing to be in what we call a heated state."

To prove this he mentions the generally accepted facts "that a mass of water at 32° contains far more heat than an equal mass of ice at the same temperature; and a mass of water gas, (steam?) at 212° contains far more heat than an equal mass of water at that temperature."

The foregoing facts illustrate the phenomenon of "latent heat" or heat not appreciable by the thermometer. But *latent heat is not heat!* It is a misnomer that should have been eradicated from scientific nomenclature long ago. The heat which melts a pound of ice is employed in *performing* a certain amount of *work* by *overcoming* the *cohesion* of the solid ice. Its subsequent liquid state is the result of this work of heat. This heat has disappeared, is no more heat; exactly as the muscular force of the locksmith's arm disappears (is latent) at night, because by eight hours of filing he has overcome the cohesion of a quantity of iron. We can not look for the work and the force spent on it at the same time.

The greater mobility of the liquid and the diminished cohesion are the equivalent of the heat that has "become latent," *i. e.*, disappeared, absolutely, utterly and entirely, as heat. In changing water back again into ice, from the liquid into the solid state, the same amount of heat must be liberated, withdrawn, or allowed to escape, as was necessary to melt it.

Water, therefore, does not contain more *heat* than ice at 32° F.; it contains more mobility, energy, potentiality —in short, more *motion*, but not motion of the heat kind.

The same relations exist between water and steam at 212° F. Here the peculiar property of the gaseous condition allows us to appreciate the nature of the difference between water and steam much more precisely than that between water and ice. "Latent heat" is here simply *expansion*, and as expansion is the work of heat it is not heat. This we can prove by confining steam or any gas in a vessel with a movable wall. If the gas just fills the receptacle and we now apply heat, a thermometer will show a rise of temperature in the interior of the vessel.

As soon as the heat reaches a certain point, so that the

expansive force of the gas equals the resistance by the weight or friction of the movable wall, the latter will move and our thermometer, indicating the temperature in the interior of the vessel, will record *a fall of temperature.* Heat has "become latent," has disappeared, because it has done work, has moved the wall.

It is, therefore, not in accordance with the facts, if Mr. Morris states that a thing may be in a heated state and yet not contain heat. Nor is it true that "as density diminishes the heat capacity increases." The true state of things is evident from the examples given. Since diminution of density is effected by heat, is the work of heat, the gas thus expanded does not contain more, but less heat. The attenuation, the change of its state of cohesion, is the action of a certain amount of heat, and this heat has "become latent," has disappeared as heat, but it nevertheless exists in the expanded gas as a greater range of mobility, as diminished density. On condensation this heat again reappears, *i. e.* the range of mobility of the gas is diminished, and the motion, potentiality, energy or whatever name Mr. Morris should prefer to apply to this *causa efficiens*, is transformed into heat. This is, by the way, the very process that is supposed to have been going on in the Laplace "Chaos," and, therefore, proves again the discrepancy between the principle of the conservation of energy and the assumption that the primordial nebula was a "fire-mist," as Mr. Larkin has correctly explained.

As to Mr. Morris' conception of the action of gravitation, it seems still more erroneous. This gentleman says: "The earth must fall towards the body with the same energy that the body displays in falling towards the earth." Now, the two fundamental laws of gravitation, as first discovered by Newton are: Attraction acts in direct proportion to mass and in indirect proportion to the square of the distance.

The statement of Mr. Morris, therefore, is absolutely false.

Nor is this all. The possibility that gravity can act lies in the space given for the fall of a body acted upon. If, therefore, a body should fall, it must be raised first to allow it space in which to fall. If by some force 100 pounds are raised to the height of one foot, this body, if unsupported, will by its fall develop the very same force as was employed to raise it previously, viz.: 100 foot-pounds. In striking on some resistance, say the surface of the earth, it will develop an amount of heat, equivalent to its mechanical force 100 foot-pounds = 100 calorics or (small) heat units. Mr. Morris ignores the element of space, in so far as it must always have been previously furnished. He says:

"The motion that exists in a falling body was not created for the purpose. It existed in the falling body in some other form and has simply been transformed, not created."

But nobody ever contended that it was created. The possibility of its fall was given to the body by some elevating force, and it is the very same force which, having existed as potentiality to fall, as long as the body was supported, is transformed into motion, into falling, as soon as the support is withdrawn. And this fall is therefore not due to "internal forces" but to gravity and the space furnished by previous raising.

But is the discrepancy laid bare by Mr. Larkin the only one existing in regard to the Nebular Hypothesis? Nay, is this hypothesis really the true history of the world, and of our planetary system in particular? Is it as free from uncertainties and as little at variance with observed facts, as an hypothesis, which has found such ready credence and such universal approval, should be?

I believe it has no claim to such confidence as has been bestowed upon it, and since I have gone so far, I might just as well state a few reasons for my conviction, which I am glad to say is shared, or rather also held, by one of our first astronomers. This I shall do further on, but at present would beg to call the attention of your readers to two other discrepancies which exist between the principle of the conservation of energy and the Nebular Hypothesis—assuming, for argument's sake, the truth of the latter.

They may be best stated by two questions, to wit:

1. What existed before "Chaos," and how was "Chaos" brought about?

2. How long and by what influence did "Chaos" remain at rest, and what cause acted on it to force it into formative action?

I have never been able to get a satisfactory answer to these questions, nor have I been successful in answering them myself. They seem to convey the impression that a most glaring discrepancy with "conservation of energy" exists in this matter, of which every reader may become convinced on mature reflection.

For, in the light of the principle of the conservation of energy, motionless matter is an impossibility, as it is totally inconceivable to our understanding in every aspect. Again: Why should attraction—if we suppose that it was dormant while the primordial nebula was forming—suddenly begin to act? What force, what cause, instigated this action at a particular moment?

It has been said, and truly, I think, that it is a very cheap and easy matter to write upon the Nebular Hypothesis. But is it also an easy thing to write *against* this hypothesis? From the fact that it is rarely done, it would appear that it is not; and yet there are dozens of facts and arguments to be brought against it. Of these I will only name the more prominent ones, without going into detail:

The eccentricity of all planetary and lunar orbits.

The various deviations of the planes of all the planetary and lunar orbits from each other.

The retrograde motion of the moons of Uranus and of that of Neptune.

The composition of the rings of Saturn.

The greater velocity of revolution of the innermost portions of the rings than that of Saturn's surface.

The greater velocity of revolution of the inner moon of Mars than that of the latter's surface.

The immense number of comets and meteorites; their great eccentricities; the considerable number that have retrograde motion; the absence of any planetary nebula, so-called, which would allow of being interpreted as an initiatory stage of the formation of a solar system.

The multiple stars, etc.

The elaboration of the various facts above stated and several others* would far exceed the proper limits of this communication—which have, indeed, been rather overstepped already. I may be allowed, however, to add what Prof. Asaph Hall, to whom the paper described in the foot-note was submitted, wrote in reply:

"To me the Nebular Hypothesis is a very doubtful thing. The facts you mention are against it. Possibly its supporters may fudge it so that it will last a little longer, but it is always unsafe to rest on a theory based largely on our ignorance."

As may be imagined, I was very agreeably surprised by this card and asked Prof. Hall's permission to make use of it in case occasion should offer. This permission the excellent gentleman first declined to give; his reasons for so doing were stated in the following language:

"Such questions as the Nebular Hypothesis will only be decided by the slow growth of observation and knowledge and not by the opinion of this man or that. I have but little faith in it. . . . ."

After some further expostulation on my part, this permission was kindly given in a letter, written December 9, 1879. Not, however, until now have I made any use of

* This I have done in a paper published in the November and December issues of the *Gaea* of the 1878, edited by Dr. Hermann Klein, at Cologne, Germany.

it, except to refer to it in a general way.* I am glad that the discussion arising from Mr. Larkin's letter has furnished such opportunity, and avail myself of it to give it to "SCIENCE" for publication. GEO. W. RACHEL.

NEW YORK, *April* 11, 1881.

MICROSCOPICAL NOTES.

Recent investigations respecting the pathological relations of diphtheria, and the discovery of a micrococcal organism in the false membrane, have made it almost certain that the morbid poison which gives rise to the disease is a parasitic organism. M. Talamon now states that he has succeeded in finding this organism in eight cases. In the condition of complete development they presented a characteristic mycelium and spores. The former are tubes with partitions from two to five thousandths of a millimetre in length. These under favorable circumstances, elongate and bifurcate, the bifurcations being characteristic in consequence of their incurved branches, like the sides of a lyre. In other conditions the mycelia do not become elongated, although they multiply so rapidly as to cover the surface of the cultivated liquid; they remain short and assume irregular forms, and give rise to numerous straight rods. The spores are of two kinds, round or oval, which may be termed the spores of germination, and rectangular spores or conidia. The latter characterize the species. They form small rectangles of various sizes, their length being sometimes fifteen thousandths of a millimetre. They may be isolated or united in festoons or zigzag chains. At first homogeneous they soon become filled with small round granules, highly refracting, and of the size of ordinary micrococci. The round or oval spores are those which by their elongation constitute the mycelium. They appear as clear points, from three to five thousandths of a millimetre in diameter, in the middle of a mass of granular material.

Animals and birds inoculated with these organisms all died developing the characteristic false membrane.

These facts are very important, and open up an entirely new field of investigation, and M. Talamon already hints that he has a clue as to the source from which the organism is derived in the case of human infection. We trust that those of our subscribers who possess microscopes will follow up the researches of M. Talamon, which promise results of the highest value to science and to humanity.

NOTES.

THE bicarbonate of soda prepared by the Solvay process contains from two to three per cent. ammonia, and is therefore not suitable for pharmaceutical use, and for certain technological purposes.

A NOVEL FERRIC HYDRATE.—C. Graebe has received from the Baden Aniline and Soda works a reddish crystalline substance deposited in cast-iron vessels in which potash has been melted. It has the same composition as hematite and gœthite, but its specific gravity is only 2.93.

CHLORINATED DERIVATIVES OF CARBAZOL.—On treating carbazol suspended in acetic acid with chlorine, the liquid turns blue, yellowish, greenish, and, lastly, red. If the reaction is then interrupted the product is trichloro-carbazol in white needles, melting at 185°. If the process is continued for ten or twelve hours, hexachloro-carbazol is produced, fusible at 225°.—W. KNECHT.

PRESENCE OF ALCOHOL IN THE SOIL, THE WATER AND THE ATMOSPHERE.—A. Muntz has previously shown that it is possible to detect exceedingly slight traces of alcohol by converting it into iodoform. On concentrating the alcohol in a small volume of water by means of fractionated distillation, and using the microscope to verify the presence of iodoform, he was able to recognize with ease 1-300,000th of alcohol mixed with water. He has since improved the process so as to detect quantities even smaller than 1-1,000,000. During the last four years he has applied this method to river, spring, and sea-water, as well as to rain and snow. The results obtained leave no doubt of the presence of a neutral body, more volatile than water, and yielding iodoform. He thinks alcohol is the hydro-carburetted body present in the atmosphere, indicated by the researches of Boussingault and De Saussure. Soils rich in organic matter yield alcohol in such proportions that its essential properties may easily be verified.

* "SCIENCE," Vol. I, p. 246, foot-note to the paper on Friedrich Mohr's Life and Works; *Scientific American Supplement* No. 266, p. 4,241, in a paper on "The Actual Figure of the Earth."

NEW SYNTHESIS OF DESOXY-BENZOIN AND CRYSENE.—MM. Graebe and Bungener have obtained desoxy-benzoin by causing the chloride of phenyl-acetic acid to react upon benzol in presence of aluminium chloride. By the same reaction, naphthalin being substituted for benzol, they produce benzyl-naphthyl-keton. They then reduce with hydriodic acid and phosphorus at 150° to 160°, and pass the vapors of the carbide thus obtained through a red-hot tube, when 4 atoms H are removed and chrysene remains.

CERTAIN PHENOMENA OF OPTICS AND OF VISION.—M. Trève mentions the fact that the flame of a lamp appears brighter, and that a vertical shaft, a post, or mast is seen more distinctly through a vertical than through a horizontal slit, whilst a house, a landscape, or the disk of the sun or moon is perceived more clearly through a horizontal slit. He finds similar differences in photographs according as the light passes from the object to the plate through a vertical or a horizontal slit, and ascribes the results to the action of diffused light.

COPAL varnish for mounting objects for the microscope has been suggested by Mr. Julien Derby of the Quekett Club, who states that Mr. Van Heurck, of Antwerp, who first used it, has met with much success in mounting diatoms with that medium. This varnish is used about the consistency of oil and should be of that brand known as "pale copal." It has about the same refractive index as balsam, and is free from bubbles. Drop the copal over the object and slightly heat over a spirit lamp. In some cases a cover can be dispensed with, as it soon takes the consistency of amber, and is hard enough to sustain wiping and brushing with a soft brush with impunity.

WIDENING OF THE RAYS OF HYDROGEN.—The nebulous expansion of the spectral rays of hydrogen, noticed on increasing the pressure of this gas in a Geissler tube, is still ascribed to the influence of the pressure, though Dr. Shuster, Secchi, and others have shown that it is not possible to alter the pressure of a gas without at the same time affecting the resistance of the medium, and in consequence the temperature of the spark which traverses it. C. Fievez has undertaken to examine separately the influence of the different agents, temperature, pressure, direction of the current, etc., which have been suggested as contributing to produce this phenomenon. He finds that the widening of the hydrogen rays is correlative to the rise of temperature. We may affirm that the temperature of a celestial body is higher than that of another if its hydrogen rays are broader.

RECIPROCAL DISPLACEMENTS OF THE HYDRACIDS.—The action of the hydracids upon the salts formed by the halogens is in general the inverse of that of the elements themselves. Thus hydriodic acid expels hydrochloric acid from the metalic chlorides and hydrobromic acid from the bromides, whilst hydrobromic acid also liberates hydrochloric acid from the chlorides. The chlorides in general are decomposed by hydrobromic acid, and this decomposition preponderates according to the thermic value of the principal action. But the bromides may also be decomposed, though less readily, by hydrochloric acid. This inverse action previously pointed out by M. Hautefeuille in the salts of silver at a red heat, and by the author in the moist way, has lately been observed anew by M. Potilizine, but it is in no way contrary to thermo-chemical principles. It results from the existence of secondary compounds, partially dissociated, which intervene with their peculiar heat of formation. The theory of these reciprocal actions and equilibria is always the same. In every case we have to do with a principal re-action, foreseen by the thermic theory, and a perturbation equally foreseen by the same theory, of which it is a necessary confirmation.—M. BERTHELOT.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at

229 BROADWAY, NEW YORK.

P. O. Box 3838.

SATURDAY, APRIL 30, 1881.

Since we last referred to Mr. Edison and his incandescent lamp, the subject has been advanced another step and the final stage of complete and unqualified success achieved; permission has been granted to the Edison Light Company, to place surface conducting wires under the streets of New York City, and in the course of the next two or three months, one large district of that city will be enjoying the full benefits of Mr. Edison's system of electrical illumination.

Taking a retrospective review of public utterances on this question during the last eighteen months, we now extend our condolence to a certain class of professed scientific experts who have maintained, from first to last, the impracticability of Edison's well-devised plans.

Never in the annals of scientific discovery has a grosser attempt been made to pervert the truth, and mislead public opinion.

As one instance among many, let us take up what is offered as a standard work of reference on this subject: "The Electric Light, its Production and Use, embodying plain directions for the working of galvanic batteries, electric lamps, dynamo-electric machines, etc.," by J. W. Urquhart, C. E., edited by F. C. Webb, M. I. C. E., M. S. T. E., London, 1880. Under the heading of "Edison's Lamps" we find "much interest has been taken in the sensational and often absurd announcements, concerning apparatus in course of perfection by Mr. T. A. Edison, of Menlo Park, New York (?), and it was in *some quarters* thought, that when he had set himself about the task of inventing an efficient subdivision of the electric light circuit, *something* would in all probability be done."

"There is little probability, however, that this lamp (the horse-shoe carbon) will prove constant. Burnt paper in various forms has been repeatedly tried before, and it is assuredly not constant, in the best possible vacuum obtainable." "We may indeed rest assured, that upon further reflection, Mr. Edison will abandon this imperfect burner" The same authors in speaking of the "Sawyer lamp," describe it as "the best incandescent lamp of this kind that has been invented."

Such being the teachings of an educational work, written by professed teachers on this subject, let them be compared with the actual results achieved, and the relative positions of the two men at this moment. Seldom has the irony of events demonstrated more forcibly that the honest work of a man is proof against the assaults of fraudulent or ignorant critics, and that the leveling influence of time always reveals the truth.

On the various attempts to imitate Edison's lamp we shall offer but a few words, for most practical inventors are usually plagued by men who endeavor to duplicate their successful inventions. If "imitation is the sincerest of flattery" we suppose Mr. Maxim is merely desirous of paying Edison a high compliment. Concerning Mr. Swan, of Newcastle, England, who professes to have perfected a horse-shoe carbon lamp, apparently identical to that of Mr. Edison's, we would draw attention to the significant fact, that in Messrs. Urquhart and Webb's work on the "Electric Light," dated as recently as April, 1880, and published in Mr. Swan's own country, not a single reference is made to the Swan electric lamp—in fact, his name does not occur in the book. This would appear to be conclusive evidence that neither Mr. Swan, nor his lamp, were known in England up to that date—unless he is included among the nameless crowd, spoken of by the authors, who had "repeatedly used burnt paper in various forms," and *who failed to secure constant results, even "in the best possible vacuum obtainable."*

CONGRESO INTERNACIONAL DE AMERICANISTAS.

We are in receipt of a pamphlet printed at Madrid, containing the official announcement of the above Congress, and instructions for those desirous of attending it. This is the fourth meeting of an International Congress for the discussion of American Archæology, and will take place on the 25th, 26th, 27th, and 28th of September next.

The object to be attained by this body is to contribute to the progress of Ethnographical, Linguistic and Historical researches relative to the two Americas, especially for the period prior to Christopher Columbus, and to bring together such persons as are interested in such studies.

Among the delegates from the United States we notice the names of Professor Spencer F. Baird, of Washington, Professor R. B. Anderson, of the University of Wisconsin; Professor J. Putnam Duncan, of the Academy of National Sciences, Davenport, Iowa, and Albert S. Gatschet, Esq., of 304 E street, N. W. Washington, D. C., to whose courtesy we are indebted for a copy of these official instructions.

Those desirous of attending this Congress, or of forwarding papers, should put themselves in communication with one of the above named gentlemen. Residents of New York City are welcome to read the prospectus at the office of "Science."

The Spanish railway authorities have consented to reduce the fares of those attending this Congress, and other concessions have been arranged. We direct the attention of those who have read early notices of this Congress to the fact that the first day of meeting has been changed from the 18th to the 22nd of September. This change has been made for the convenience of those who would attend two other International Congresses which meet at about the same time, one at Berlin and another at Venice.

THE UNITY OF NATURE.

By the Duke of Argyll.

VII.

ON THE MORAL CHARACTER OF MAN CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

(*Continued*).

It breaks down the presumption that whatever is most savage is therefore probably the most ancient. And then, when we come to think of it, this idea, from being vague and general, rises into suggestions which are definite and specific. On the great fundamental subject of the relation of the sexes, conclusions not less important than those respecting cannibalism and infanticide are forced upon our conviction. We have seen that the cruel treatment of the female sex is almost universal among savages, and that it is entirely unknown among the lower animals. It is in the highest degree improbable and unnatural to suppose that this habit can have been primeval. But the same considerations carry us a great deal farther. They raise a presumption in favor of the latter origin of other habits and customs which are not confined to the savage state, but have prevailed, and do now prevail, among nations comparatively civilized. There can have been no polygamy when as yet there was only a single pair, or when there were several single pairs widely separated from each other. The presumption, if not the certainty, therefore is, that primeval Man must have been monogamous. It is a presumption supported by the general equality of the sexes in respect to the numbers born, with only just such an excess of the male sex as tends to maintain that equality against the greater risks to life arising out of manly pursuits and duties. Thus the facts of Nature point to polygamy as in all probability a departure from the habits of primeval times. Like considerations set aside, as in a still higher degree unnatural and improbable, the primeval rank of other customs of which the historians of human culture tell us, and probably tell us truly, that there are many surviving traces among the existing customs of men. Thus "marriage by capture" cannot have been primeval. It may be very ancient: but it cannot possibly have arisen until the family of Man had so multiplied and scattered, that it had become divided into tribes accustomed to act with violence towards each other. And then as regards a custom still more barbarous and savage, namely, that of polyandry, and that which is now euphemistically called "communal marriage," apart from the strong presumption in favor of primeval monogamy, they are stamped by many separate considerations as corruptions and as departures from primeval habits. In the first place, all such customs are fatally injurious to the propagation of the race. In the second place, they are unknown in the animal world. In the third place, their origin can be assigned, in many cases, if not with certainty at least with the highest probability, to one cause, and that is the previously-acquired habit of female infanticide. But as regards this last habit, besides the certainty that it cannot have been primeval, we know that it has often arisen from customs such as the exorbitant cost of marriage portions, which can only have grown up under long developed and highly artificial conditions of society.

But powerful as all these separate considerations are to raise at least adverse presumptions against the primeval rank of the worst and commonest characteristics of savage life, the force of these considerations is much increased when we find that they are closely connected together, and that they all lead up to the recognition of a principle and a law. That principle is no other than the principle of Development; that law is no other than the law of Evolution. It is a curious misunderstanding of what that law really is, to suppose that it leads only in one direction. It leads in every direction in which there is at work any one of the "potential energies" of Nature. Development is the growth of germs, and according to the nature of the germ so is the nature of the growth. The flowers and fruits which minister to the use of Man have each their own seed, and so have the briars and thorns which choke them. Evil has its germs as well as good, and the evolution of them is accompanied by effects to which it is impossible to assign a limit. Movement is the condition of all being, in moral as well as in material things. Just as one thing leads to another in knowledge and in virtue, so does one thing lead to another in ignorance and vice. Those gradual processes of change which arise out of action and reaction between the external condition and the internal nature of Man have an energy in them of infinite complexity and power. We stand here on the firm ground of observation and experience. In the shortest space of time, far within the limits even of a single life, we are accustomed to see such processes effectual both to elevate and degrade. The weak become weaker and the bad become worse. "To him that hath more is given, and from him that hath not is taken even that which he seemeth to have." And this law, in the region of character and of morals, is but the counterpart of the law which prevails in the physical regions of Nature, where also Development has its double aspect. It cannot bring one organism to the top without sinking another organism to the bottom. That vast variety of natural causes which have been grouped and almost personified under the phrase "Natural Selection," are causes which necessarily include both favorable and unfavorable conditions. Natural Rejection, therefore, is the inseparable correlative of Natural Selection. In the battle of life the the triumph of one individual, or of one species, is the result of causes which bring about the failure of another. But there is this great distinction between the lower animals and man,—that in their case failure involves death and complete extinction, whilst in his case it is compatible with prolonged survival. So far as mere existence is concerned, the almost infinite plasticity and adaptability of his nature enable him to accommodate himself to the hardest lot, and to the most unfavorable conditions. Man is the only animal whose possible distribution is not limited to narrow, or comparatively narrow, areas, in consequence of exclusive dependence upon particular conditions of climate and of productions. Some such conditions of a highly favorable kind may, and indeed must, have governed the selection of his birthplace and of his infancy. But when once born and fairly launched upon his course, it was in his nature to be able to prevail over all or over most of the limitations which are imposed upon the lower animals. But it is this very power of adaptation to unfavorable circumstances which involves of necessity the possibility of his development taking an equally unfavorable direction. If he can rise to any level, so also can he descend to any depth. It is not merely that faculties, for the exercise of which there is no call and no opportunity, remain dormant, but it is also, that if such faculties have already been exercised,

they may and often do become so stunted that nothing but the rudiments remain.

With such immense possibilities of change inherent in the nature of man, we have to consider the great element of Time. Strangely enough, it seems to be very commonly assumed that the establishment of a great antiquity for the human race has some natural, if not some necessary, connection with the theory that primeval Man stood on some level far lower even than any existing savage. And no doubt this connection would be a real one if it were true that during some long series of ages Development had not only been always working, but had always been working upwards. But if it be capable of working, and if it has been actually working, also in the opposite direction, then the element of time in its bearing upon conditions of modern savagery must have had a very different operation. For here it is to be remembered that the savage of the present day is as far removed in time from the common origin of our race as the man who now exhibits the highest type of moral and intellectual culture. Whether that time is represented by six thousand, or ten thousand, or a hundred thousand years, it is the same for both. If therefore the number of years since the origin of Man be taken as a multiplier in the processes of elevation, it must be taken equally as a multiplier in the processes of degradation. Not even on the theory which some hold, that the human species has spread from more than one centre of birth or of creation, can this conclusion be affected. For even on this hypothesis of separate origins, there is no reason whatever to suppose that the races which are now generally civilized are of more recent origin than those which are generally savage. Presumably, therefore, all the ages which have been at work in the development of civilization have been at work equally in the development of savagery. It is not possible in the case of savagery, any more than in the case of civilization, that all those ages have been without effect. Nor is it possible that the changes they have wrought have been all in one direction. The conclusion is, that neither savagery nor civilization, as we now see them, can represent the primeval condition of Man. Both of them are the work of time. Both of them are the product of Evolution.

When, however, this conclusion has been reached, we naturally seek for some understanding--some definite conception—of the circumstances and conditions under which development in Man has taken a wrong direction. No similar explanation is required of the origin of civilization. This is the development of Man's powers in the natural direction. Great interest, indeed, attaches to the steps by which knowledge has been increased, and by which invention has been added to invention. But there is no mystery to be encountered here—no dark or distressing problem to be solved. This kind and direction of development is all according to the constitution and course of things. It is in harmony with all the analogies of Creation. Very different is the sense of painful wonder with which we seek an explanation of the wretched condition of Man in many regions of the globe, and, still more, with which we seek the origin of the cause of all the hideous customs which are everywhere prevalent among savage men, and which often, in their ingenuity of evil, and in the sweep of their destructive force, leave it a wonder that the race survives at all.

There are, however, some considerations, and some facts, on which we may very safely advance at least a few steps towards the explanation we desire. Two great causes of change, two great elements of Development or Evolution, have been specified above—namely, the external conditions and the internal nature of Man. Let us look at them for a little separately, in so far as they can be separated at all.[1]

[1] The argument which follows was urged in a former work on "Primeval Man." It has been here re-written and re-considered with reference to various objections and replies

It is certain that external or physical conditions have a very powerful, and sometimes a very rapid, effect both on the body and on the mind of Man. The operation of this law has been seen and noted even in the midst of the most highly civilized communities. There are kinds of labor which have been found to exert a rapid influence in degrading the human frame, and in deteriorating the human character. So marked has been this effect, that it has commanded the attention of Parliaments, and the course of legislation has been turned aside to meet the dangers it involved. Moreover, our experience in this matter has been very various. Different kinds of employment, involving different kinds of unfavorable influence, have each tended to develop its own kind of mischief, and to establish its own type of degradation, The particular conditions which are unfavorable may be infinitely various. The evils which arise out of the abuses of civilized life can never be identical with the evils to which the earlier races of Mankind may have been exposed. But the power of external conditions in modifying the form, and in molding the character of men, is stamped as a general law of universal application.

In connection with this law, the first great fact which calls for our attention is the actual distribution of Mankind in relation to the physical geography of the globe. That distribution is nearly universal. From the earliest times when civilized men began to explore distant regions, they found everywhere other races of men already established. And this has held true down to the latest acquisitions of discovery. When the New World was discovered by Columbus, he found that it must have been a very old world indeed to the human species. Not only every great continent, but, with rare exceptions, even every habitable island has been found peopled by the genus HOMO. The explorers might find, and in many cases did actually find, everything else in Nature different from the country of their birth. Not a beast, or bird, or plant,—not an insect, or a reptile, or a fish, might be the same as those of which they had any previous knowledge. The whole face of Nature might be new and strange—but always with this one solitary exception, that everywhere Man was compelled to recognize himself—represented, indeed, often by people of strange aspect and of strange speech, but by people nevertheless exhibiting all the unmistakable characters of the human race.

In ancient times, before the birth of physical science, this fact might not appear so singular and exceptional as it really is. Before Man had begun to form any definite conceptions as to his own origin, or as to his place in Nature, it was easy to suppose in some vague way that the inhabitants of distant regions were "Aborigines," or as the Greeks called them "Autocthonoi"—that they were somehow native to the soil, and had sprung from it. But this conception belongs essentially to that stage and time when tradition has been lost, and before reasoning has begun. Those who refuse to accept the Jewish Scriptures as in any sense authoritative, must at least recognize them as the records of a very ancient and a very sublime Cosmogony. That Cosmogony rests upon these four leading ideas—first, that the globe has been brought to its present condition through days of change; secondly, that from a state which can only be described as chaos, it came to be divided into sea, and land, and atmosphere; thirdly, that the lower animals were born first,—Man being the last as he is the highest product of Creation; fourthly, that he appeared first at one place only in the world, and that from one pair has all the earth been overspread.

It is remarkable that in this general outline of events, and especially in the unity of Man's origin, the progress of discovery, and those later speculations which have outrun discovery, are in strict accordance with the tradition recorded by the Jewish Prophets. There are, indeed, some, scientific men who think that different races

of men represent different species—or, at least, that if Man be defined as one species, it is a species which has spread from more than one place of origin. But those who hold to this idea are men who stand outside the general current of scientific thought. The tendency of that thought is more and more to demand unity and simplicity in our conception of the methods of creation, and of the order of events through which the birth of species has been brought about. So strong is the tendency, and so intimately connected is it with the intellectual conceptions on which the modern theory of Development has been founded, that Mr. Darwin himself, and Mr. Wallace, who may be said to be joint-author with him of that theory, both lay it down as a fundamental postulate, that each new organic Form has originated, and could only originate, at one place. This doctrine is by no means a necessity of thought, nor is it a necessary consequence of the theory of Development. It rests mainly on the doctrine of chances, and that doctrine may be wholly inapplicable to events which are governed not by accident but by law. It is, however, a postulate of the particular form of that theory which Mr. Darwin has adopted. It is not always easy to reconcile this postulate with the existing distribution over the globe of animal forms. But it is not absolutely inconsistent with the facts so far as we know them; and it is interesting to observe how universally and tacitly it is assumed in all the current explanations of the history of Creation. On this point, therefore, of the unity of Man's origin, those who bow to the authority of the most ancient and the most venerable of traditions, and those who accept the most imposing and the most popular of modern scientific theories, are found standing on common ground, and accepting the same result.

And when we come to consider a very curious subject, namely, the configuration of the habitable continents of the globe, we find that this configuration stands in a very intelligible relation to the dispersion of Mankind from a single center. If, indeed, we could suppose that the earliest condition of our race was a condition of advanced knowledge in the useful arts, there would be no difficulty to solve. The great oceans of the world are now the easiest highways of travel, and, consequently, of dispersion. The art and the science of navigation has made them so. But we cannot imagine that this art or this science was known to our forefathers of a very early age. Various means of crossing narrow waters, from the use of solid logs of wood to the use of the same logs when hollowed out, and so to the use of canoes and boats, were in all probability among the very earliest of human inventions. But not the less would it have been impossible with these inventions to cross the Atlantic, or the Indian Ocean, or even many of the more limited tracts of sea which now separate so many habitable regions. Some other solution must be found for the problem presented by the fact that the earliest navigators who traversed those seas and oceans have always found the lands on the other side already colonized, and in some cases thickly inhabited by races and nations which had made considerable advances in civilization. Yet, this problem presents no serious difficulty in accepting the unity of the human race, when it is regarded in the light of physical geography. The distribution of the larger tracts of land and sea upon our planet is very singular indeed. Attached to the southern Pole there is no mass of land which stretches so far north as to enter the latitudes which are even moderately temperate. In the centre of the Antarctic Circle there is probably a great continent. But it is a continent where volcanic fires burst here and there through surfaces which are bound in perpetual ice. Round that vast Circle roll the continuous waves of an Ocean vexed by furious storms, and laden with the gigantic wrecks of immeasurable fields and cliffs of ice. In the northern hemisphere, round the Arctic Circle, on the contrary, everything is different. There land-masses begin, which stretch southward without a break through all the temperate and through all the torrid zones on both sides of the Equator. Then, again, all these great continents of the globe, as they extend towards the south, become narrower and narrower, and so tend to become more and more widely separated from each other by vast oceanic spaces. Towards the north, on the contrary, all these continents converge, and at one point, Behring's Straits, they approach so near each other that only a space of some forty miles of sea intervenes between them. The result is, that in the northern hemisphere there is either a continued connection by land, or a connection severed only by comparatively narrow channels, between all the great inhabited continents of the world. The consequences of this as bearing on the dispersion of Mankind are obvious at a glance. If, for example, Man may be supposed to have been born in any part of Western or Central Asia, it is easy to see how his earliest migrations might lead him without serious difficulty into every one of the lands in which his children have been actually found. The Indian peninsula was at his feet. A natural bridge, as it were, would enable him to penetrate the Arabian deserts, and would conduct him by the glorious valley of the Nile into the heart of the continent of Africa. Eastwards he had before him the fertile tracts of China, and beyond the narrow passage of Behring's Straits lay that vast continent which, when rediscovered from the West, was called the New World. Again, beyond the southern spurs of the great Asiatic Continent there lay an archipelago of magnificent islands, with comparatively narrow seas between them, and connected by a continuous chain with the continental islands of Australasia. The sea-faring habits which would spring up among an insular population,—especially in an archipelago where every volcanic cone and every coral reef rising above the waves was rich in the products of a bounteous vegetation,—would soon lead to a rapid development of the arts of navigation. When these were once acquired, there is no difficulty in accounting for the gradual dispersion of the human race among the beautiful islands of the Pacific. Across its comparatively peaceful waters it is not improbable that even rude navigators may have made their way at various times to people the western shores of the continent of America.

It is true indeed that the science of geology teaches us that the distribution of sea and land has been immensely various in different epochs of the unmeasured ages which have been occupied in the formation of our existing world. And it may be urged from this that no argument on the methods of dispersion can be based with safety upon that distribution as it now is. There is not much force, however, in this plea. For it is equally true that the evidence afforded by geology is in favor of the very great antiquity of the principal land-masses, and of the great oceanic hollows which now divide them. The antiquity of these is almost certainly much greater than the antiquity of Man. The fauna and the flora of the principal continents indicate them to have been separated since a period in the development, or in the creation of species, long anterior to any probable estimate of the time of Man's appearance. Even if that appearance dates from the Miocene epoch in geology,—which is an extreme supposition,—no great difference in the problem of the dispersion of our species would arise. Since that time indeed it is certain that great subsidences and elevation of land have taken place. But although these changes have greatly altered the outlines of sea and land along the shores of Europe and America, there is no reason to believe that they could have materially affected, either injuriously or otherwise, the earlier migrations of Mankind.

But although the peculiar physical geography of the globe makes it easy to understand how, from a single centre, it must have been quite possible for a creature with the peculiar powers and faculties of Man to distribute himself, as he has actually been found distributed over

every habitable region of the world, it is most important to observe the very adverse conditions to which, in the course of this distribution, particular portions of the human family must have been, and to which we do now find them actually exposed.

The "New World"—the American continent—is that which presents the most uninterrupted stretch of habitable land from the highest northern to the lowest southern latitude. No part of it was without human inhabitants when the civilized children of the Old World first came upon it, and when, from its mountain tops, they first "stared on the Pacific." On its extreme north there was the Eskimo or Inuit race, maintaining human life under conditions of extremest hardship, even amid the perpetual ice of the Polar regions. On the extreme south—at the opposite extremity of the great American continent—there were the inhabitants of Cape Horn and of the island off it, both of which project their desolate rocks into another of the most inhospitable climates of the world. Let us take this case first—because it is a typical one, and because it happens that we have from a master-hand a description of these people, and a suggestion of the questions which they raise. The natives of Tierra del Fuego are one of the most degraded among the races of mankind. How could they be otherwise? "Their country," says Mr. Darwin, "is a broken mass of wild rocks, lofty hills, and useless forests; and these are viewed through mists and endless storms. The habitable land is reduced to the stones of the beach. In search of food they are compelled to wander unceasingly from spot to spot; and so steep is the coast that they can only move about in their wretched canoes." They are habitual cannibals, killing and eating their old women before they kill their dogs, for the sufficient reason, as explained by themselves, "Doggies catch others: old women, no." Of some of these people who came round the *Beagle* in their canoes the same author says: "These were the most wretched and miserable creatures I anywhere beheld. They were quite naked, and even one full-grown woman was absolutely so. It was raining heavily and the fresh water, together with the spray, trickled down her body. In another harbor not far distant, a woman who was suckling a new-born child, came one day alongside the vessel and there remained out of mere curiosity, whilst the sleet fell and thawed on her naked bosom, and on the skin of her naked baby. These poor wretches were stunted in their growth, their hideous faces bedaubed with white paint, their skins filthy and greasy, their hair entangled, their voices discordant, and their gestures violent. Viewing such men, one can hardly make one's self believe that they are fellow-creatures and inhabitants of the same world." Such are the facts, or one aspect of the facts, connected with this people. But there are other facts, or another aspect of the same facts, not less important which we have on the same evidence. Beneath this crust of savagery lay all the perfect attributes of humanity—ready to be developed the moment the unfavorable conditions of Fuegian life were exchanged for conditions which were different. Captain Fitzroy had, in 1830, carried off some of these poor people to England, where they were taught the arts and the habits of civilization. Of one of those who was taken back to his own country in the *Beagle*, Mr. Darwin tells us that "his intellect was good," and of another that he had a "nice disposition."

Let us look now at the questions which the low condition of the Fuegians suggests to Mr. Darwin. "Whilst beholding these savages, one asks whence have they come? What could have tempted, or what change compelled, a tribe of men to leave the fine region of the North, to travel down the Cordillera or backbone of America, to invent and build canoes which are not used by the tribes of Chili, Peru, and Brazil, and then to enter one of the most inhospitable countries within the limits of the globe?"

These questions of Mr. Darwin, it will be observed, assume that Man is not indigenous in Tierra del Fuego. They assume that he has come from elsewhere into that savage country. They assume farther that his access to it has been by land. They assume that the progenitors of the Fuegians who first came there were not skilled navigators like the crew of the *Beagle*, able to traverse the Atlantic or the Pacific in their widest and stormiest expanse. These assumptions are surely safe. But these being accepted, it follows that the ancestors of the Fuegians must have come from the North, and have passed down the whole length, or a great part of the length, of the American continent. In other words, they must have come from regions which are highly favored into regions of extremest rigor. If external circumstances have any influence upon the condition of Man, this great change cannot have been without effect. Accordingly, Mr. Darwin at once, instinctively as it were, connects the utter savagery of the Fuegians with the wretched conditions of their present home. "How little," he says, "can the higher powers of the mind be brought into play! What is there for imagination to picture, for reason to compare, for judgment to decide upon." It is in perfect accordance with this view that on every side of them, and in proportion as we pass northwards from their wretched country, we find that the tribes of South America are less wretched, and better acquainted with the simpler arts. None of the depressing and stupefying conditions which attach to the present home of the Fuegians can be alleged of the regions in which some distant ancestors of the Fuegians must have lived. In Chili, in Peru, in Brazil, in Mexico, there are boundless tracts in which every condition of nature, soil, climate, and productions, are comparatively as favorable to men as they are unfavorable on the desolate shores of Cape Horn and Tierra del Fuego. Yet one or other of these many well-favored regions must have been on the line of march by which the Fuegian shores were reached. One and all of them present attractions which must have induced a long encampment, and must have made them the home of many generations. Why was that march ever resumed in a direction so uninviting and pursued in a destination so desolate and so miserable?

But the moment we come to ask this question in respect to the Fuegians, we find that it is a question which arises equally out of the position and life of many other portions of the human family. The northern extremity of the American continent presents exactly the same problem as the southern. If it is impossible to suppose that Man was first created, or born, or developed in Tierra del Fuego, it is not less impossible to suppose that he had made his first appearance on the frozen shores of Baffin's Bay. Watching at the blow-hole of a seal for many hours in a temperature 75° below the freezing point, is the constant work of the Inuit hunter. And when at last his prey is struck, it is his greatest luxury to feast upon the raw blood and blubber. To civilized man it is hardly possible to conceive a life so wretched, and in some aspects at least so brutal, as the life led by this race during the continual night of the Arctic winter. Not even the most extravagant theorist as regards the possible plurality of human origins can believe that there was a separate Eskimo Adam. Man, therefore, is as certainly an immigrant into the dreary regions round the Pole as he is an immigrant to the desolations of Cape Horn. But the whole conditions of his life there are necessarily determined by the rigors of the climate. They are conditions in which civilization, as it has been here defined, is impossible. And the importance of that definition is singularly apparent in the case of the Eskimo. Although essentially uncivilized, he is not, in the ordinary sense of the word, a savage. Many of the characteristics usually associated with that word are altogether wanting in the Eskimo. They are a gentle, inoffensive, hospitable, and truthful race. They are therefore a conspicuous example of the fallacy of supposing that there is any necessary connection between a backward condition of knowledge in the useful arts, and violent dispositions, or

ferocious and cruel habits. Men are not necessarily savage because they may use flint hatchets, or because they may point their arrows and their spears with bone. Nevertheless, the condition of the Eskimo, although not savage, is almost the type of the merely uncivilized condition of Mankind. It is a condition in which not more than a few families can ever live together, and in which, therefore, large communities cannot be formed. A few simple and some very curious rules of ownership are all that can represent among them the great law-giving instinct which lives in Man. Agriculture cannot be practiced, nor even the pasturing of flocks and herds. Without fuel, beyond the oil which feeds their feeble lamps, or a few stray logs of drift timber, the Eskimo can have no access to the metals, which in such a country could not be reduced from their ores, even if these ores were themselves obtainable. The useful arts are, therefore, strictly limited to the devising and making of canoes and weapons of the chase. There is no domestic animal except the dog, and dogs too, like their masters, must have been brought from elsewhere. These are all conditions which exclude the first elements of what we understand by civilization. But every one of these conditions must have been different with the progenitors of the Eskimo. If they were immigrants into the regions within the Arctic Circle, they must have come from the more temperate regions of the South. They must have been surrounded there by all the natural advantages of which their descendants are now deprived. To what extent these ancestors of the Eskimo may have profited by their very different and more favored position, we cannot know. They may have practiced such simple agriculture as was practiced by the most ancient races which have left their traces in the Swiss Lake dwellings. They may have been nomads, living on their flocks and herds, as the Laplanders and Siberians actually are who in the Old World live in latitudes only a little farther south. They may have been people who, like the ancient but unknown Mound-builders in the Southern and Western States of America, had developed a comparatively high civilization. But one thing is certain, that they must have lived a life wholly different from the life of the Eskimo, and that they must have had completely different habits. Whatever arts the father knew, suited to more genial climates, could not fail to be forgotten by the children, in a country where the practice of them was impossible.

The same question, therefore, which Darwin asks in respect to the inhabitants of the extreme south of the American continent, arises in respect to the inhabitants of its extreme north—What can have induced any people to travel along that continent in a direction more and more inhospitable, and at last to settle in a country where nearly one-half the year is night, and where, even during the short summer, both sea and land are mainly occupied by ice and snow?

But, again, we are reminded that there are other cases of a similar kind. The African continent does not extend so far south as to reach a severe southern latitude. In that continent, accordingly, beyond the frequent occurrence of deserts, there is nothing seriously to impede the migrations of Man from its northern towards its southern extremity; nor is there anything there to subject them when they had reached it to the worst conditions. Accordingly we do not find that the predominant native races of Southern Africa rank low in the scale of humanity. Those among them, however, which are or were the lowest in that scale, were precisely those who occupied the most favorable portion of the country and are known as Bushmen. Of these it is well ascertained that they are not a distinct race, but of kindred origin with the Hottentots, who were by no means so degraded. On the whole, therefore, the question how men could ever have been induced to live where we actually find them, does not press for an answer so much in respect to any part of the continent of Africa, with the exception of a few tribes whose present habitat is exceptionally unfavorable.

There is, however, another case of difficulty in respect to the distribution of Mankind, which in some respects is even more remarkable than the case of the Fuegians, or the case of the Eskimo. We have seen that the great Asiatic continent, though it does not itself extend beyond latitudes which are favorable to human settlement, is practically prolonged through a continuous chain of islands into the regions of Australasia. Every part of those regions was found to be inhabited when they were discovered by civilized man; and it is universally admitted that the natives of Australia, and the natives of Tasmania, are or were (for the Tasmanians are now extinct) among the very lowest of all the families of Man. Now the physical conditions of the great islands of Australasia are in many respects the most remarkable on the surface of the globe. Their peculiar fauna and flora prove them to be of great antiquity as islands in the geological history of the earth. That is to say—their beasts, and their birds, and their vegetation are so widely separate from those of all other regions, that during long ages of the total time which has elapsed since they first appeared above the ocean, they must have been as separate as they are now from all other habitable lands. Their beasts are, indeed, related—closely related—to forms which have existed during certain epochs in many other portions of the earth's surface. But those epochs are so distant, that we are carried back in our search for creatures like them to the times of the Secondary Rocks—to the horizon of the Oolite. Speaking of the poverty and of the extremely isolated character of the Australian Mammalia, Mr. Wallace says: "This class affords us the most certain proofs that no part of the country has been united to the Asiatic continent since the latter part of the Mezozoic period of geology."[2] Of the vast series of creatures which elsewhere have been created, or born, or developed, since that epoch, including all the higher members of the Mammalian Class, not one existed in Australasia until they were introduced by Europeans. Among the grasses there were none which by cultivation could be developed into cereals. Among the beasts there was not one which was capable of domestication. There were no apes or monkeys; no oxen, antelopes, or deer; no elephants, rhinoceroses, or pigs; no cats, wolves or bears; none even of the smaller civits or weasels: no hedgehogs or shrews; no hares, squirrels, or porcupines, or dormice."[3] There was not even a native dog; and the only approach to, or representative of, that wonderful animal, was a low, marsupial beast, which is a mere biting machine, incapable of affection for a master, and incapable even of recognizing the hand that feeds it. In the whole of Australia, with the exception of a few mice, there was not one single mammal which did not belong to this low Marsupial Class, whilst some others belonged to a class still lower in the scale of organization, the class called Monotremata. Strange forms astonished our first explorers, such as the Ornithorynchus and the Echidna—forms which combined features elsewhere widely separated in the animal kingdom—the bills of Birds, the spines of Porcupines, the fur of Otters, and the feet of Moles. Nothing analogous to these relics of an extinct fauna had been known to survive in any other part of the world. Yet in the midst of this strange assemblage of creatures, without any representative of the animals which elsewhere surround him, the familiar form of Man appeared, low, indeed in his condition, but with all the inalienable characteristics of his race. It is true, that everywhere the gap which separates Man from the lower animals is enormous. Nothing bridges, or comes near to bridging it. It is a gap which has been well

[2] "Australasia," by Alfred R. Wallace, p. 51.

[3] "Australasia," by Alfred R. Wallace, p. 51.

called a gulf. But in Australasia the breadth and depth of this gulf is rendered more conspicuous by the association of Man with a series of animals absolutely wanting in those higher members of the Mammalian Class which elsewhere minister to his wants, and the use of which is among the first elements of a civilized condition. Alone everywhere, and separate from other beings, Man is most conspicuously alone in those strange and distant lands where his high organization is in contact with nothing nearer to itself than the low marsupial brain.

To those who connect the origin of Man with the theory of Development or Evolution, in any shape or in any form, these peculiar circumstances respecting the fauna of Australasia indicate beyond all doubt that Man is not there indigenous. They stamp him as an immigrant in those regions—a wanderer from other lands. Nor will this conclusion be less assuredly held by those who believe that in some special sense Man has been created. There is something more than an incongruity in supposing that there was a separate Tasmanian Adam. The belief that the creation of Man has been a special work is not inconsistent with the belief that in the time, and in the circumstances, and in the method of this work, it had a definite relation to the previous course and history of Creation—so that Man did not appear until all these lower animals had been born, which were destined to minister to his necessities, and to afford him the means and opportunities for that kind of development which is peculiarly his own. On the contrary, this doctrine of the previous creation of the lower animals, which is, perhaps, more firmly established on the facts of science than any other respecting the origin of Man, is a doctrine fitting closely into the fundamental conceptions which inspire the belief that Man has been produced by operations as exceptional as their result. And so it is, that when we see men inhabiting lands destitute of all the higher Mammalia, which are elsewhere his servants or companions—destitute even of those productions of the vegetable kingdom, which alone repay the cultivation of the soil, we conclude with certainty that he is there a wanderer from some distant lands, where the work of creation had been carried farther, and where the conditions of surrounding Nature were such as to afford him the conditions of a home.

We see, then, that the question asked by Mr. Darwin, in respect to the Fuegians, is a question arising equally in respect to all the races who inhabit regions of the globe, which from any cause present conditions highly unfavorable to Man. Just as Mr. Darwin asked, what could have induced tribes to travel down the American continent to a climate so rigorous as Cape Horn?—just as we have asked, on the same principle, what could have induced men to travel along the same continent in an opposite direction till they reached and settled within the Arctic Circle?—so now we have to ask, what could have induced men to travel from Asia, or from the rich and splendid islands of the Eastern Archipelago, and to take up their abode in Australasia?

In every one of these cases the change has been greatly for the worse. It has been a change not only involving comparative disadvantages, but positive disabilities—affecting the fundamental elements of civilization, and subjecting those who underwent that change to deteriorating influences of the most powerful kind.

It follows from these considerations as a necessary consequence that the present condition of the Australian, or the recent condition of the Tasmanian, cannot possibly be any trustworthy indication of the condition of their ancestors, when they lived in more favored regions. The same argument applies to them which, as we have seen, applies to the Fuegians and the Eskimo. If all these families of Mankind are the descendants of men, who at some former time inhabited countries wholly different in climate, and in productions, and in all the facilities which these afford for the development of the special faculties of the race, it is in the highest degree improbable that a change of habitat so great should have been without a corresponding effect upon those over whom it passed. Nor is it a matter of doubt or mere speculation that this effect must have been in the highest degree unfavorable. The conclusion, therefore, to which we are led is, that such races as those which inhabit Australasia, are indeed the results of development, or of evolution—but of the development of unfavorable conditions, and of the evolution of the natural effects of these. Instead of assuming them to be the nearest living representative of primeval Man we should be more safe in assuming them to represent the widest departure from that earliest condition of our race which, on the theory of Development, must of necessity have been associated at first with the most highly favorable conditions or external Nature.

DOLBEAR ON THE NATURE AND CONSTITUTION OF MATTER.

A CRITIQUE.

There appeared in "SCIENCE" a series of three papers[1] by Professor A. E. Dolbear which contain such new and somewhat startling ideas on the nature and constitution of matter that an interesting controversy was to be expected. Nearly six months have, however, passed without any objections having been raised to any of the Professor's statements, some of which seem to me quite strange and of rather peculiar mathematics withal. I now, with no little hesitation enter a protest against some of these statements. The subject of the constitution of matter is so intricate, so complicated, beset with so many difficulties on the one hand, while on the other our means of dealing with it are so inadequate, our methods of investigation so imperfect that, as Maxwell says, all we can do is to make hypotheses and see how far our facts and phenomena bear them out. This being so, I believe that whenever a particularly bold hypothesis is made and conclusions are drawn therefrom by anyone without having made a most careful comparison with all the principal phenomena of matter, the humblest student of this fascinating department of physical science has a right to command a most vigorous halt, and to examine whether he who assumes to guide is himself sufficiently acquainted with the intricacies and windings of the road not to lead his followers into the dismal swamps of metaphysical vagaries. I therefore claim for myself that right, lest what I have to say might be construed as too presumptuous.

In my review I shall, in the main, touch upon and discuss the points I desire to examine, in the order in which they occur in the Professor's papers. To begin, then, with the first paper, Section II, I shall devote a little attention to the equation $E' = \varepsilon \frac{mv^2}{2}$ which the Professor says expresses the total energy of an atom. It seems an altogether gratuitous assumption to give to the expression for the total energy of an atom the same form that Clausius gives for the total energy of a molecule. In the molecule we have the motion of translation and also the motion or motions of its parts relative to its centre of mass; but of the atom we cannot make the same assertion. Clausius was justified, by mathematical deductions from experimental data, to assume that the total energy of the molecule is proportional to the energy of agitation; but that does by no means justify the assumption that the same form of function also expresses the total energy of the atom, for here all experimental data are wanting. We may, however, reasonably conclude that the form of this function for the atom must differ somewhat from that for the molecule, as the motions of the atom must, of necessity, be much more intricate and complex

[1] "On Some Needed Changes and Additions to Physical Nomenclature," Vol. I., p. 238; "On Matter as a Form of Energy," Vol. II., p. 49, and "On the Amplitude of Vibration of Atoms," Vol. II., p. 146.

than those of the molecule. Granting the correctness of the expression for argument's, sake I must confess that I do not understand how the Professor gets the expression $E' - E = \varepsilon$ given under 3, in his "Table of Forms of Energy." If ε in the expression $E' = \varepsilon \frac{m v^2}{2}$ is anything it certainly must be the ratio $\frac{E'}{E}$ where $E = \frac{m v^2}{2}$ is the energy of agitation of an atom. By subtraction we obtain $E' - E = \varepsilon \frac{m v^2}{2} - \frac{m v^2}{2} = \frac{m v^2}{2} (\varepsilon - 1)$ and not ε as the Professor would lead us to believe. While I regard it simply a gratuitous assumption to give the expression for the total energy of an atom, and that for the total energy of a molecule the same form—because we have no experimental evidence whatever to justify us to believe that the conditions of the atom resemble those of the molecule—I believe that the equation $E' = \varepsilon \frac{m v^2}{2}$ in which ε is *internal* energy is utterly incorrect. ε in this expression is not at all analogous to β in $\frac{1}{2} \beta m v^2$ the expression for the total energy of a molecule as given by Maxwell. Here β is the numerical ratio of the total energy to the energy of agitation, an abstract, while ε is internal energy, a concrete. Here let me ask what is energy times energy. The form $E' - E = \varepsilon$ is undoubtedly correct. From this by substitution we get $E' = \frac{m v^2}{2} + \varepsilon$ and not $\varepsilon \frac{m v^2}{2}$.

The statement "Latent heat, specific heat, and specific inductive capacity, are all involved in (that factor?) ε," is certainly not correct. Latent heat is work performed upon some body, and is, according to Clausius, partly internal and partly external. The external work is performed upon surrounding material systems. The internal work is, in general, composed of two parts—one expended upon the molecules in expanding the body from one state of aggregation to another, the other part is expended upon the parts of the molecule. It is only this last portion which can affect the atom as such, and which can in any way be involved in ε. Similarly we find that specific heat is also work performed, and that, too, of a complex nature. Specific inductive capacity seems to me to belong to an altogether different class of phenomena.

In regard to the ether the Professor makes some very curious statements. He says that he knows nothing of the specific properties of the ether, yet in the same sentence is the statement "ether is not matter," as if this were a generally accepted view. If the ether is not matter, what is it? There are two ways of looking at matter—the subjective or metaphysical, and the objective or physical. Metaphysically defined matter is anything which has extension or occupies space. For the physical definition I quote Maxwell[2]: "Hence, as we have said, we are acquainted with matter only as that which may have energy communicated to it from other matter, and which may, in its turn, communicate energy to other matter." Again, he says: "Energy cannot exist except in connection with matter." Whether, then, we accept the metaphysician's definition or the physicist's, we must regard ether as matter; for it certainly has extension and occupies space, and it certainly receives from other matter, transmits and imparts to other matter energy. That Maxwell regarded ether as matter, appears from the following quotation, taken from the same work and page as the preceding: "Hence, . . . we conclude that the *matter* which transmits light is disseminated through the whole of the visible universe." The italics are mine. Professor Dolbear, furthermore, tacitly assumes ether to have mass, as will appear hereafter.

Again, the Professor says: "Furthermore, as atoms differ in mass so will their rates of vibration differ when they possess the same absolute amount of energy. Velocity, in this case, will be equal to amplitude $a\,b$, the space point c passes over during one vibration. If m and m' be two atoms of different masses having equal energy of vibration, then $E = \frac{m v^2}{2} = \frac{m' v'^2}{2}$ and $\frac{m}{m'} = \frac{v'^2}{v^2}$ that is the square of their velocities is inversely as their masses, so that wave-length in the ether will vary as the mass of the atom." This is certainly very curious logic and mathematics. The statement may be true, and the investigations of Lecoq de Boisbaudran even furnish some evidence in its favor, but the mathematical proof offered by the Professor does not justify any such conclusion. v and v' are, according to his own statement, amplitudes of vibration; when, then, the atoms of different masses have equal energy, the proportion $\frac{m}{m'} = \frac{v'^2}{v^2}$ simply proves that the squares of the amplitudes of vibration are inversely as the masses. In what manner the rate of vibration and wave-length in ether follows from this relation of mass to amplitude the Professor does not make clear. In order to make the above conclusion of Professor Dolbear correct, we must have the further condition, $\frac{v'^2}{v^2} = \frac{n'}{n}$ where n and n' are the relative number of vibrations of m and m' in equal times. One of the most fundamental equations of motion is unquestionably $v = \frac{s}{t}$. Hence, as the amplitude $a\,b$ is a space passed over in a given time, we can make it equal to v only by making t unity. Similarly we can make the amplitude of m' equal to v' only by making t unity. If now we wish to compare the velocities and masses of the two atoms we can certainly not use different units of time to determine those velocities; and we get, according to the Professor's statement, the self-contradictory result that two atoms, which make each one vibration in equal times yet have different rates of vibration. To make the problem more general let us take two atoms of masses m and m'. Let them make respectively n and n' vibrations of amplitudes, a and a' in unit of time. The time of one vibration of m will be $\frac{1}{n}$ and of m', $\frac{1}{n'}$. Substituting these values successively for t, and a and a' successively for s in the equation of motion, we have $v = \frac{a}{\frac{1}{n}} = a n$ and $v' = \frac{a'}{\frac{1}{n'}} = a' n'$ combining $\frac{v}{v'} = \frac{a n}{a' n'}$, or the velocities are proportional to the products of the amplitudes by the number of vibrations in unit time. Combining this with the Professor's proportion we have $\frac{m}{m'} = \frac{a'^2 n'^2}{a^2 n^2}$.

To obtain from this the relation $\frac{m}{m'} = \frac{\lambda}{\lambda'}$, λ and λ' being wave-lengths, we must fulfil the condition $\frac{a'^2 n'^2}{a^2 n^2} = \frac{n'}{n}$ or $\frac{n}{n'} = \frac{a'^2}{a^2}$. If, then, two atoms of the masses m and m' have equal energy, and the relation $\frac{n}{n'} = \frac{a'^2}{a^2}$ holds n and n', being the respective number of vibrations in unit time, and a and a' corresponding amplitudes, the relation $\frac{\lambda}{\lambda'} = \frac{m}{m'}$ in which λ and λ' are wave-lengths will follow. For we will then have, as above shown, $\frac{m}{m'} = \frac{n'}{n}$. We also have $\lambda = \frac{v}{n}$ and $\lambda' = \frac{v}{n'}$. From these we obtain $\frac{\lambda}{\lambda'} = \frac{n'}{n}$ and, hence, $\frac{m}{m} = \frac{\lambda}{\lambda'}$.

[2] "Matter and Motion," p. 93.

Whether or not the relation $\frac{n}{n'} = \frac{a'^2}{a^2}$ holds in any particular case can, it would seem, be determined only by experiment. So, too, the fact of the equal absolute energy of vibration of two atoms. Our experimental methods are, however, as yet far from competent to deal with either question, and until they are it is certainly premature to build up speculative hypotheses.

Every student of molecular science knows how great is the temptation to build hypotheses which are to account for all the physical and chemical relations of matter. We can read between the lines of nearly all our recent writers in this department of science their secret belief that chemical phenomena are probably but a complex phase of mechanical phenomena, and that all matter is probably one. Nor are facts justifying such views altogether wanting. Probably no chemist would be bold enough to say in how far such phenomena as, for instance, the solution of ammonia, carbon dioxide, and many other gases in water are of purely chemical and how far of purely physical nature. There are many other phenomena in which similar difficulty would be felt. The phenomena of adhesion and cohesion are such that it does not require a very great stretch of the imagination to suppose that they may be but different phases of what we call chemical union. But to pass from such general and indefinite speculations to suppositions in regard to the mechanical conditions which will account for all these phenomena and all the properties of matter upon purely mechanical principles is a long and, indeed, a bold stride. As the temptation to make this attempt is great, so ought our caution to be great in making the attempt. Professor Dolbear's immediate predecessor in this attempt is Professor Norton. His hypothesis of two atmospheres, one attractive, the other repellant, surrounding each atom, is too artificial, and in being in opposition to the "Kinetic Theory of Gases," is probably too much out of sympathy with the tendency of modern thought to make many converts. Not so, however, with Professor Dolbear's speculations. Their great fundamental simplicity, as well as their thoroughly Kinetic nature, make them dangerous to healthy progress in molecular science unless they can maintain their right of being by accounting for at least the chief and fundamental phenomena of matter. I shall now attempt to apply the touch-stone to them. In Section IV. of his first paper Professor Dolbear advances an hypothesis of chemical union founded on the analogy to a vibrating body which, as is well known by reducing the average density of the atmosphere, causes light bodies to cling to it by atmospheric pressure. We are told that precisely the same conditions exist in the ether near a vibrating atom; that the average density of the surrounding ether is lessened, and that by extraneous pressure another atom vibrating synchronously with the first would attach itself thereto, and the molecule would be formed, etc., etc. I would like to ask how Prof. Dolbear can consistently speak of the density of ether, which, he says, is not matter. Now, in this idea of density there is implicitly the idea of mass, for density, as every one knows, is the mass or amount of matter in unit volume. But, disregarding this inconsistency, it is certainly very bold induction, if induction it can be called, to attribute chemical union to a lessening of density of ether due to atomic vibrations because a vibrating tuning-fork attracts light bodies when brought sufficiently near. In the professor's hypothesis the atoms (vortex-rings) vibrate about a circle as figure of equilibrium, and consequently have four points of maximum displacement or minimum density of the ether. As a consequence of this, each atom must attract other atoms capable of attaching themselves to it at four points. To judge from his diagrams, the Professor believes that atoms unite only in two-dimensional space, *i.e.*, that the centres of all the atoms lie in the same plane. Such a distribution of the atoms would render any closed structure such as a saturated molecule an impossibility, for the peripheral atoms would constantly attract further atoms as long as they vibrate, and other atoms vibrating synchronically with them are present. If, on the other hand, the atoms are arranged in tri-dimensional space, having their centres in planes, say, at right angles to one another, the simplest molecule and the only really stable one would have to contain six atoms whose planes of rotation form the faces of a cube. A further possible supposition is that the atoms would arrange themselves in parallel planes with their centres in a line at right angles to these planes. The first of these suppositions, as already indicated, would not allow the formation of saturated molecules, and it would seem that all chemical union, as we know it, could not exist, for it would evidently be altogether a matter of chance how atoms grouped themselves in regard to numbers, so that we could not always obtain like results of union under precisely like conditions. The second supposition is also inconsistent with chemical facts, for we have molecules of two, three, four and five atoms, as well as others containing hundreds. The third supposition is also untenable, for from Helmholtz's mathematical investigations and Tait's experiments we know that two vortex-rings, when they move axially in the same direction alternately, pass through each other one expanding, the other contracting, while when moving axially in opposite directions they both expand moving slower and slower, but never meet. This is, according to Tait, about all we know experimentally or mathematically in regard to the action of one vortex ring upon another. It is certainly a little strange that Prof. Dolbear, in framing his hypothesis, completely ignores these known facts, and relies on a far-fetched analogy. Serious as are these difficulties, they are by no means the most serious. If experimental evidence is worth anything, we must believe that elementary molecules, with a few exceptions, consist of two atoms, which are, as far as we can judge, exactly alike. Furthermore, we find that in all chemical reactions we can deal with nothing less than the molecule; we know and can deal with the atom only as a part of a molecule, and not as an independent existence. When chemical union takes place between two elements, there is simply an interchange of atoms between the molecules. The difference between the molecules of an element, and those of a compound, is simply this, that the atoms of elementary molecules are all alike, while those of a compound molecule are unlike. I repeat all these fundamental and well-known chemical facts and deductions, to show how singularly inadequate Prof. Dolbear's hypothesis is to account for even the most simple chemical facts. According to his hypothesis, the atoms whose rates of vibration are most exactly alike, must form the most stable molecules. Consequently, the atoms of an element must cling more firmly together than can those of two different elements, and chemical union between the elements becomes impossible. Did the atoms of elements exist as individuals, and not as parts of molecules simply, synchronism of vibrations might be a possible supposition to account for chemical union; but as the case stands, we must reject any such hypothesis as precluding all combination between atoms of different elements. Setting aside even this difficulty, how are we to account by synchronous vibrations for the liberation of energy in the form of heat and light, which accompanies most chemical unions. These forms of energy are, according to the Professor himself, altogether due to vibrations of the atoms and these same vibrations cause the union. Now, how can they both cause the union and be produced by it? Does this not look a little like *perpetuum mobile?* Had the Professor tried to explain adhesion and cohesion by molecular vibration his position would undoubtedly be much stronger. We know that molecules are complex and that there must be motion of their parts relative to the centre of mass of

the molecule. As there is no good reason for supposing the motions of these parts or atoms to be rather in one plane than another, we must admit the possibility of motion in all planes. The vibrations would, however, probably be in three planes at right angles to one another in all molecules of more than three atoms; and would, consequently, have six points of maximum displacement and minimum density of the surrounding ether. Molecules of two and three atoms might possibly vibrate in two or only one plane. As molecules are not vortex-rings, though possibly groups of vortex-rings, the analogy to a vibrating tuning fork becomes much closer than in the case of a vibrating vortex-ring, and we are much more justified in trying to make application of the hypothesis. Prof. Dolbear's analogy thus modified can, I think, be made a very fair working hypothesis to explain adhesion, cohesion and even crystallization. The phenomena of surface tension of liquids and capillary action find a reasonably fair explanation upon this hypothesis, and possibly also those of osmosis, dialysis and occlusion. But even here such an hypothesis meets with many difficulties and we must exercise extreme caution, and must gather further experimental evidence before committing ourselves to its acceptance.

In his second paper the Professor tells us that the vortex-ring theory assumes that matter is a *form of energy*, etc. Never having been so fortunate as to have had access to Sir William Thomson's original memoir, I know his celebrated hypothesis only through interpretations of others. From these interpretations I have always supposed that this hypothesis assumes that all matter is essentially one; and that the elements, as we know them, are portions of this common matter imbued with vortex-motion, thus forming vortex-rings variously knotted, whose energy is non-interchangeable with other forms of energy provided the vortex-rings are formed and exist in a perfect or frictionless fluid. If the fluid is not quite perfect, not quite frictionless, the vortex-rings must gradually be destroyed and their energy must be transformed. The uniform material substratum, if I understand the hypothesis correctly, consists of smaller and simpler vortex-rings which are also the particles or atoms of the ether. If, then, I comprehend the positions, the non-transformability of the energy of the vortex atoms and also their permanence, *i. e.* the persistence of our elements depend upon the perfect fluidity of the ether. Whether the ether is perfectly frictionless or not science is, I think, hardly ready to answer. To call "*matter a form of energy* not interchangeable with other variable forms" is, under the circumstances and from the meaning of the terms employed, to take extraordinary liberties with language. Physically regarded, energy is, to strip the term of all technicalities, matter in motion. Then Professor Dolbear's statement becomes matter, is a form of matter in motion, which is hardly intelligible. Again we are told "The energy of a mass of matter varies as the square of the velocities, but the *properties* of the mass vary with the form of the energy, that is to say the physical properties of a heated body are not identical with those of the same body when it is cool, but possesses the same amount of energy in free path motion." Exactly what this sentence means is, I must confess, beyond my comprehension. One thing, however, seems certain, that it expresses an idea directly opposed to the "Mechanical Theory of Heat" and the "Kinetic Theory of Gases" in the statement that a cool body "possesses the same amount of energy in free path motion" as the same body when heated. If this be so, what becomes of $\frac{vp}{\tau} = \frac{v'p'}{\tau'}$ for gases, and what of the "Thermo-dynamic Scale of Temperature."

In regard to the assumption $\frac{mv^2}{2}$ = atomic weight and the calculations based thereon, I will merely remark that if the groups having the same m or those having the same v showed any family likeness or any gradual variation of properties as do Mendelejeff's periods and groups, then they would be worthy of consideration. As it is, however, they seem mere jugglery with figures. That the atoms of the elements have a "common form differing arithmetically from each other in size and velocity" is utterly inconsistent with the well-known facts and phenomena of quantivalence or valency of atoms. There would have to be two forms at least one for artiad, and one for perissad atoms. I think for the present, at least, we must reject this idea of simplicity and still follow Sir William Thomson.

In the third paper we read, "There is now sufficient evidence for the belief that the Kinetic energy of atoms and molecules consists of two parts, one of which is the energy of translation or free path, the other of a change of form due to vibrations of the parts of the atom or molecule toward or away from its centre of mass. The pressure of a gas is immediately due to the former while the temperature depends solely upon the latter." To the first sentence of this quotation I object, because atoms and molecules are treated as if similar, for which assumption we have no evidence. The second sentence contains the very strange idea that the temperature of a gas is due only to the internal energy of the molecule. Maxwell in his "Theory of Heat" Chap. XXII, under "Specific Heat at Constant Volume" says: "Since the product pv is proportional to the absolute temperature, the energy is proportional to the temperature." By energy Maxwell here means, as appears from the context, what Prof. Dolbear would call total energy. From this it appears that Prof. Dolbear's statement can hardly be correct. If we remember that Maxwell speaks of molecules and Prof. Dolbear of atoms the latter's statement becomes still more doubtful. The assumption that "these two forms of energy must indeed be equal to each other in a gas under uniform conditions," upon which all the Professor's calculations in his third paper are based, can easily be disproved. The Kinetic energy of agitation of a molecule is $\frac{1}{2}\ mv^2$ and the (total) energy is "$\frac{1}{2}\ \beta\ mv^2$ where β is a factor always greater than unity and probably equal to 1.634 for air and several of the more perfect gases." Hence the internal energy is $\frac{1}{2}$ (.634 mv^2.) This, of course, invalidates all the Professor's calculations.

Having extended my remarks far beyond what I originally intended, I shall touch upon only one more point, though I find various other difficulties in the Professor's speculations. The last paragraph of the third paper begins: "As at absolute zero each atom is quite independent of every other atom, that is, matter has not a molecular structure, etc." Now, I would like to ask the Professor how he knows this. Such a state of affairs would indeed make the absolute zero a more than singular point in the curve of the properties of matter.

BUFFALO, N. Y., *April* 20, 1881. WM. H. DOPP.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

INTRA-MERCURIAL PLANETS.

To the Editor of "SCIENCE:"

I wish to say that in the sketch given to "SCIENCE," No. 35, p. 95, the position of Professor Swift's Vulcans is very nearly as they were put down by Professor Swift himself on a map that now hangs in my room at the Naval Observatory.

As to negative evidence there is something to be said on both sides of the question. When extraordinary discoveries are reported they are to be severely examined and carefully criticised. If the observations on which

the discoveries rest are conflicting among themselves, and if the probability of such discoveries is rendered small by long and careful series of independent observations, we are justified in waiting for further evidence before we accept the alleged discoveries as true. The ways in which an observer may be deceived are numerous. In 1878 an astronomer wrote me that he had discovered a satellite of Venus that revolved around the planet in thirty seconds. I expressed some doubt and advised him to examine his telescope and the eye pieces. He did so and was candid enough to inform me that the satellite he had discovered was nothing but a "ghost."

If any astronomer who is familar with astronomical observations and their discussion, will examine the reports on the Vulcans supposed to have been discovered during the eclipse of 1878, and will notice how the reports were changed from time to time, he will find good reasons for doubt. Certainly this matter is not to be settled by assertion. If there are Vulcans of the fourth and fifth magnitudes which attain an angular distance of from three to seven degrees from the sun, they ought to be found easily. A. HALL.

Washington, April 25, 1881.

THE SOLAR PARALLAX.

To the Editor of "SCIENCE":

From the American photographs of the Transit of Venus, as presented in part the first of "Observations of the Transit of Venus, December 8, 9, 1874, Made and Reduced Under the Direction of the Commission Created by Congress," I have obtained, for the value of the solar parallax, $8.883'' \pm 0.034''$ corresponding to a distance between the centres of the sun and the earth equal to 92,028,000 miles. D. P. TODD.

WASHINGTON, *April* 26, 1881.

ASTRONOMY.

MOUNT ETNA OBSESVATORY.—The *Memoirs* of the Italian Spectroscope Society contains an illustration of the Observatory of Mount Etna, showing that work upon the building has progressed as rapidly as could have been expected, when we consider the difficulties to be overcome in the transportation of materials, etc. Every effort is being made to finish the Observatory by 1882, and provide it with a director and staff both of astronomers and meteorologists. W. C. W.

Messrs. Houzeau and Lancaster, the Director and Librarian of the Bruxelles Observatory, are performing an extremely valuable service to astronomers by the preparation of a general bibliography of Astronomy. Two volumes have thus far appeared, the second of which is just published, and is devoted to memoirs which have appeared in scientific periodicals, and in the publications of the various academies. Four topics are included in this volume, Spherical Astronomy, Theoretical Astronomy, Celestial Mechanics, and Physical Astronomy. The only thing which even approximates the completeness of the present work, is the catalogue of the library of the Poulkova Observatory, a new edition of which has been in course of preparation for several years past. The Bruxelles work, however, has the advantage of being a general bibliography, and not limited to the contents of any one library, however extensive. O. S.

MICROSCOPICAL NOTES.

At our suggestion, Mr. Lockwood, of New York City, who has already devoted considerable attention to the application of Photography to the various branches of science, now proposes to make arrangements for photographing Microscopical Preparations.

The objects will be enlarged by very perfect and powerful objectives, and photographed while thus enlarged.

Those possessing microscopes will at once notice the great advantage to be secured by such an arrangement. Few possess the skill to produce a drawing from a microscopic object, while the amount of detail involved in sketching anatomical preparations, can be mastered by few who are not professed artists.

When Mr. Lockwood's arrangements are complete a microscopist, for a moderate amount, will be enabled to have a perfect copy of any microscopic preparation, and as many duplicate as he requires to circulate among specialists, or his friends. Should he desire to publish the result of his researches, Mr. Lockwood can then photograph the object directly on the wood block, ready for the hand of the engraver.

The chief value of the use of Photography in such a case lies in the fact that such drawings, being prepared by the hand of nature, their integrity cannot be impeached, and that any charge of exaggeration or error cannot be maintained.

When Mr. Lockwood's arrangements are complete we will announce the fact in our microscopical column, but in the interval would be glad to hear from those who are likely to avail themselves of these facilities for promoting microscopical research.

NOTES.

Les Mondes proposes to apply the photophone to the study of the *aurora borealis*.

ON THE GALVANIC POLARIZATION PRODUCED BY METALLIC DEPOSITS.—The polarization of copper, employed as negative electrode in a solution of sulphate of zinc, is never null, as Lipmann believes, in cases where the solution contains traces of a salt of copper, and that the deposit of zinc is exceedingly slight and invisible. On the contrary, it has a value which may differ much, and which is so much the greater the smaller the quantity of a copper-salt contained in the solution, and the less the time which has passed from the moment when the polarizing current was interrupted.—D. MACALUSO.

ON THE ELECTROMOTIVE FORCE OF VOLTAIC ARC.—When an electric flux is established between two conductors of the same nature by means of a gaseous medium, which is commonly the vapor thrown off by their substance, the inequality of temperature of those portions of the conductors which are contiguous to such a medium appears to be a general fact. It seems not less probable that the extremity by which the positive electricity arrives, possesses the higher temperature. This is observed in a remarkable degree in the production of the voltaic arc between two carbons, by means of a current of constant direction. The idea of ascribing to this phenomenon a thermo-electric origin is not novel. According to the application of the principle of the equivalence of heat to electric phenomena, an electromotive force acting in the inverse direction of the current, corresponds to a disengagement of heat at the point of junction of two heterogeneous substances.—M. F. P. LE ROUX.

MAGNETIC ACTION UPON THE FLUORESCENT LIGHT PRODUCED BY THE NEGATIVE DISCHARGE IN AN EXHAUSTED SPACE.—If we take a well-exhausted cylindrical tube, with rectilinear electrodes placed in its axis, the fluorescent light formed by the cathodic rays consists, as is well known, of a green cylinder bounded by a circle. This circle undergoes transpositions if a magnet is allowed to act upon the discharge. It can be shown that these, whether simple or complicated cases, may be explained by the following hypothesis:—The cathodic rays, emanating from the negative electrode, pass on in a straight direction, and the current moves from the anode to the sides of the cathodic space, and from thence to the negative electrode. The magnet acts upon these currents according to Ampère's rule.—K. DOMALIP.

BOOKS RECEIVED.

COMPENDIUM OF MICROSCOPICAL TECHNOLOGY; A guide to Physicians and Students in the use of the Microscope, and in the preparation of Histological and Pathological specimens. By CARL SEILER, M. D. Published by D. G. Brinton, Philadelphia, 1881.

The author of this work has a high reputation for preparing mounted specimens for Microscopical study, and therein gives short and clear descriptions of his own methods, which have given such satisfactory results. The reader is, therefore, not perplexed by being instructed in the various methods suggested by many authorities, but a clear line of conduct is indicated for him by Dr. Seiler, which may be relied on as being satisfactory.

The work is written for medical students, and for that reason the usual subject matter found in Manuals of Microscopy is altogether omitted, neither are descriptions given of tissues, and the student is referred for histological details to works devoted to histology.

Without intending to cast any reflection on the body of the work, we are inclined to consider the appendix the most valuable part of Dr. Seiler's book. In it the author presents a short, concise, and, at the same time, comprehensive classification of the more common tumors and other neoplasms in tabular form; these, indeed, will be welcome to the student of pathological histology. The author claims to have exercised great care in its compilation, and to have introduced all the accepted modern views on the subject, so as to bring it up to the standard of the present time.

POPULAR LECTURES ON SCIENTIFIC SUBJECTS. By H. HELMHOLTZ, Professor of Physics in the University of Berlin. Translated by E. ATKINSON, Ph. D., F. C. S. Second Series. D. Appleton & Co. New York, 1881.

The present volume presents a series of addresses and lectures delivered by Professor Helmholtz during a period of six years, from 1871 to 1877. The contents show that the following subjects are treated:

1. An address delivered before the Leibnitz meeting of the Academy of Sciences, 1870. In memory of Gustav Magnus.

2. A lecture on the Origin and Significance of Geometrical Axioms, delivered at Heidelberg, 1870.

3. The substance of a series of lectures on the relation of optics to painting, delivered at Cologne, Berlin and Bonn.

4. Lecture on the Origin of the Planetary System, delivered in 1871.

5. An address delivered in 1877, on the Anniversary of the foundation of the Institute for the Education of Army Surgeons: or, Thought in Medicine.

Perhaps the only popular paper in the series is that "On the Origin of the Planetary System," in which the various hypotheses connected with the subject are explained in simple and familiar language. Professor Helmholtz appears to have handled this subject in a manner which must have been a source of delight to a mixed audience. Touching on extinct suns he explained that a time would arrive when our own sun would cease to develop the heat which is a source of vitality to this earth. But he explained that 17,000,000 of years would lapse before this "intensity of sunshine, would be diminished, and that circumstances may even prolong this period."

Looking forward to such a period when our sun shall be extinguished, Professor Holmholtz observes that considering the wonderful adaptability to the conditions of life which all organisms possess, who knows to what degree of perfection our posterity will have developed in 17,000,000 of years, and whether our fossilized bones will not seem to them as monstrous as those of *Ichthyosaurus* now do; and whether they, adjusted for a more sensitive state of equilibrium, will not consider the extremes of temperature, within which we now exist, to be just as violent and destructive as those of the older geological times appear to us? Yea, even if sun and earth should solidify and become motionless, who could say what new worlds would not be ready to develop life? Meteoric stones sometimes contain hydro-carbons; the light of the heads of comets exhibits a spectrum which is most like that of the electrical light in gases containing hydrogen and carbon. But carbon is the element, which is characteristic of organic compounds, from which living bodies are built up. Who knows whether these bodies, which everywhere swarm through space, do not scatter germs of life, wherever there is a new world, which has become capable of giving place to organic bodies? And this life we might perhaps consider as allied to ours in its primitive germ, however different might be the form which it would assume in adapting itself to its new dwelling place.

Probably the lectures "On the Relation of Optics to Painting" and the address "On Thought in Medicine" are the most valuable productions of Professor Helmholtz to be found in this volume, and as space for their proper examination cannot be used in this notice, references will be again made to them on another occasion.

This work should find a place in every library of standard works of Literature.

A MOST successful experiment in theatre illumination was tried on March 30 and 31, at the Athenæum of the Rue des Martyrs, Paris, with the Werdermann incandescent light. The peculiarity of it is that it can be graduated at will for scenic effects, either by introducing resistance coils or varying the velocity of the Gramme machine.

EFFECT OF TEMPERATURE UPON THE ELECTRICAL RESISTANCE OF SELENIUM.—Mr. Shelford Bidwell, in the *Philosophical Magazine* for April, gives an account of some experiments made on the above subject. He says: "The room being 14° Centigrade, a selenium cell was immersed in turpentine at 8° C. There was a great and sudden fall in the resistance. The temperature was then gradually raised. In passing from 8° to 24° the resistance steadily increased; from 24° upwards it rapidly diminished. For this cell, therefore, the resistance is greatest at 24° C. Five other cells were afterwards submitted to the same operation, and their resistance was found to be greatest at temperatures of 23°, 14°, 30°, 25°, and 22° respectively."

ELECTRIC TRANSMISSION OF FORCE FOR WORKING CRANES.—According to E. Hospitalier, the use of hydraulic pressure for the transmission of the power required in working cranes in docks, involves a loss which, in some cases, may reach 88 per cent. This evil is entirely obviated, in addition to a great simplification of the entire plant, by means of electric transmission of power, which enables the original steam power to be fully utilised even when the crane is raising much less than its maximum load. If we reduce the loading of a crane the electro-magnetic machine which drives it will have less work to do, and will revolve more rapidly, and the stronger counter-currents thus produced will react upon the dynamo-electric machine in such a manner that there is a less current produced, and a less demand is made upon the steam-power. The only question is, how the current is to be divided into several unequal branches capable of being varied in strength at any moment.—*La Lumière Electrique.*

ON THE STATIONARY ELECTRIC CURRENT IN CONDUCTIVE SURFACES, AND ON THE GALVANIC RESISTANCE OF PSILOMELAN.—Hugo Meyer, in the first portion of this memoir, discusses the ramification of the current, and the calculation of the resistance of flat plates. The experimental results agree with calculation. In the second part the author's experimental results agree with calculation. In the second part the author examines the resistance of thin plates of psilomelan, and obtains results antagonistic to those of Braun, who found the resistance decrease under the influence of an induction current.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at
TRIBUNE BUILDING, NEW YORK.
P. O. Box 3838.

SATURDAY, MAY 7, 1881.

Dr. H. J. Detmers, of Chicago, has forwarded to us a communication of considerable importance, which will doubtless be read with interest both on this continent and in Europe.

In 1877 the Commissioner of Agriculture reported that during the previous year, the loss due to farm animals dying from infectious and contagious diseases amounted to $16,653,428, of which amount two-thirds, or over $11,000,000, were due to loss of swine. But as this report included returns from only half of the United States, the above sum was, of course, far below the actual losses of the year.

Congress having appropriated $10,000 for defraying the expenses of a commission to investigate the causes which produced these contagious and destructive diseases, and, if possible, to discover remedies, the matter was placed in various hands to conduct the inquiry.

Among those who have received instructions from the Department of Agriculture, Dr. H. J. Detmers has shown considerable skill in attacking the problem, and the results of his work have developed several discoveries of great biological significance.

Although working with inferior microscopical appliances, he soon found that a particular kind of Bacterium was always present in cases of swine plague, and he has been able, apparently, to prove by actual experiment that these Bacteria were the active principle of contagion.

The early investigations of Dr. Detmers were given in the Report of the Agricultural Department for 1878. Since this time Dr. Detmers has, with considerable industry, continued his investigations under more favorable circumstances; for armed with new objectives made by Mr. Tolles, of Boston, with powers of definition equal to anything yet manufactured to aid human vision, a new revelation has resulted from their use.

The latest discoveries of Dr. Detmers we are able to place before our readers in another column of this issue. Possibly the conclusions drawn in this paper may be criticised, and our columns will be open to any exceptions taken on scientific grounds, but our readers must unite in giving credit to Dr. Detmers for the very thorough and exhaustive treatment which this subject has received at his hands.

The researches of Pasteur in a somewhat similar direction, which have been reported in this journal, suggest to us that Dr. Detmers should, like Pasteur, endeavor to arrest the spread of Hog Cholera by a system of vaccination. Dr. Detmers shows in his present paper that by cultivating the Bacterian infecting element, a contagious principle is secured which by inoculation produces a very mild form of the disease. Could not advantage be taken of this fact in the direction we have indicated?

We are glad to announce that Hog Cholera is rapidly becoming a thing of the past, and has decreased since 1878 so rapidly that at the present time *it is difficult to obtain badly infected specimens* for scientific experimental purposes. This fact, which is communicated to us by Dr. Detmers in a private letter, will be welcome news to those interested in this extensive industry and to the public generally. In Dr. Detmer's report, which we publish this day, it should be noticed that he states that in 1878 the malignant or fatal form (with ulcerous tumors) was found in about 75 *per cent.* of all fatal cases (in Illinois), whereas now their occurrence is probably limited to about 5 *per cent. of all* cases.

Thus the Swine-plague is now under control and is rapidly disappearing. These results are clearly due to the wise policy of publicly making known the evil and the danger, and promptly taking precautionary measures. Let the credit then be given where it is due, even if extended to that much abused Department of Agriculture at Washington, which first raised a voice of warning and secured funds from Congress to "investigate and determine the causes, and if possible *to discover remedies*" of one of the most destructive diseases that ever assailed domestic animals.

Of the Trichinæ trouble we have but a few words to offer, as it can be more profitably described without reference to other subjects. We may, however, observe that it is one of the least formidable of diseases found in hogs, and can probably be eradicated, if proper measures are taken. It is useless to assert that it does not exist, and the only common sense view of the case to be taken, is to acknowledge the evil and root it out. Action should be taken by Boards of Trade to at once gather statistics by proper examinations. If, as they assert, there are no Trichinæ in Ameri-

can hogs, the fact will be demonstrated; if, on the contrary, Trichinæ are found, the extent of the trouble will be known and steps can be taken to protect the industry by systematic examination. We believe that the presence of Trichinæ in pigs is confined to certain districts; if so, it can be localized, and the work of investigation gradually reduced within certain limits, and eventually, by proper precautions, the evil would be entirely removed.

MOUNTAIN ELEVATION, AND CHANGES OF TEMPERATURE, IN GEOLOGY.

By Samuel J. Wallace.

It seems a very little thing for heat and cold to play over the face of a continent. But light and unnoticed as the creeping of fate it goes on forever; and the foundations of the everlasting hills are in its iron grasp. Cold and heat. What should a rock-ribbed continent care for them? What do they do?

In latitude 40° to 50° a yearly change of ten degrees of heat penetrates the upper strata to considerable depths; and the expansion of various kinds of stone for 10° varies from one to three feet in twelve thousand; making, say, one foot to the mile, which across North America is half a mile.

This is an always recurring and resistless force of outward thrust. It is probably mostly compensated for in its habitual recurrence by elasticity, slippages of strata on others, and by fissures; as well as by the fact that the expansion of solid strata is sometimes less from the deep drift or soil protecting them. But, still, as the superior force is outward, without anything to compel a full return in winter, and as the expansion is less below and greater above, the continued tendency is to push the upper strata forward over others toward the margins of extended plains, with a creeping motion, tending to force up bendings, folds and faults, and to raise mountains and plateaus slowly; and even to accumulate such strain or tension as to cause earthquakes and volcanos.

Though, as Dana and others think, there has been a singular persistence in the general features of deep oceans and of continental tables, yet, great portions of the tabular areas have had their depressions and upheavals from the sea. What must have occurred in such cases?

If a tract of sea-bed is covered by an arctic current at 32°, the cold must finally penetrate to very great depths. Then, should the polar current by any means be shut off, and a warm current flow over it, the temperature would certainly be raised several degrees, and produce an expansion which would find relief in raising mountain ridges, or in arching up its own or other regions. This might go on slowly till great areas were elevated from the ocean.

Rising from the sea, also, would increase the temperature very much, to heave up mountains and plateaus, or still other lands from the sea. This result it seems would have to occur, because of the great depths to which the expansion would reach, and because there would exist no provision for relief of the tension, such as the repeated yearly expansion would work out for itself.

It seems these results must flow from what we already know, whether there is or not, any other cause of elevation. There are some further considerations that may be noticed here.

Where a deep ocean trough bearing an arctic current lies along beside a continent it would form a fixed barrier to such expansions, and probably a chain of mountains would be forced up along it, together with volcanos and earthquakes. The region of least yearly change and greatest cold is said to be in the northern edges of America and Siberia, and the bar connecting them across the pole. From the ends of this region the annual change increases southward and laterally. Singularly, the principal mountain systems of the northern hemisphere seem as if raised by forces or thrusts radiating from this bar and its ends. In America, as Dana shows, the original core of the continent was V-shaped, with its two ridges facing the end of that cold bar between them. And the later elevations preserve parallelism to these original lines, as if showing thrusts from that bar and from each other. In Europasia occur continuations of the same parallelism of elevations as facing thrusts radiating from the sides and the other and broader end of the same cold bar, to the areas of greatest annual changes southward, with still increased force and complexity.

In the southern hemisphere the bases of thrust seem as if, on the contrary, they were the three great ocean beds. And the great mountain systems of the world seem as if raised by thrusts of force radiating from these great northern and southern centers of land and ocean, opposing each other, together with some cross thrusts over broad areas of land. This feature of opposition between the northern land thrusts and the southern ocean beds, brings some of the principal lines of elevation in the northern hemisphere into diagonal courses, except where sweeping around the northern projections of the oceans, especially that of the Indian ocean, and its former connection west to the Atlantic south of Europe.

The present Alleghany system seems to have been raised by the elevation of the Mississippi Valley from the sea during and after the Carboniferous period; the Rocky Mountains by that of the plains, later; and the Alps by that of Northern Africa and Northern Europe, although previous elevations existed.

The familiar example of ice creeping up the shores of ponds and lakes, from repeated changes of temperature in winter, illustrates the principle of such elevations, the walled lakes of Iowa being special illustrations; and interesting observations have been published, showing from fixed levels that oscillations of level do occur from changes of temperature.

REMARKS ON A PATHOGENIC SCHIZOPHYTE.*

Prof. H. J. Detmers.

When about two and a half years ago it became my duty to investigate the prevailing Swine-plague, the so-called Hog-cholera, I first endeavored to ascertain the nature and the cause of that disease, and to accomplish my object, made numerous post-mortem examinations, and paid special attention to the microscopic examinations of the blood and of the morbid products and morbid tissues. Although the microscope at my disposal at the beginning of my investigation is only a small No. VIII Hartnack stand with three Hartnack and Prazmowski objectives—a 1 inch, a ¼ inch, and a 1-9th inch imm. and correctives—and consequently not a strictly first-class instrument, and in its performance by no means equal to the work of a Tolles or a Zeiss, I soon became convinced that the blood, the morbid products, and the morbid tissues of the diseased and dead animal invariably contained, while fresh, and not tainted by putrefaction, a certain kind of Schizophytes or bacteria. The same presented themselves in three different shapes, namely as small globular bacteria or Micrococci, as Zoöglœa-masses or clusters, imbedded in, or kept together by, a viscous mass, and as little rods or filaments. I soon found that all three forms belong to the same organism, and represent only different stages of development. The first or globular form predominated in the blood, the second in the morbid tissues—for instance, in the diseased portions of the lungs and in the lymphatic

* Read before the State Microscopical Society, of Illinois, April 8th, 1881.

glands—and the rods occurred in greatest numbers in such morbidly changed parts and morbid products—for instance, in the ulcerous tumors of the intestines—as are accessible to atmospheric air and other external influences.

The constant occurrence of these Schizophytes soon made it appear probable that their presence is not merely accidental, but that the same, very likely, are connected with, and characteristic of, the morbid process of the disease. To get at the facts was one of my principal endeavors. How far I have succeeded I leave to others to judge.

Careful and repeated macroscopic and microscopic examinations of the tissues, but especially of the lungs, which, by the way, are always more or less affected by the morbid process of Swine-plague, soon revealed the fact that the principal morbid changes are brought about in the following way: The finer capillary blood vessels become obstructed or plugged, the more fluid portions of the blood exude into the tissues—in the lungs principally and at first into the lobules, and then into the interlobular connective tissue—some, and particularly in young animals not seldom but a great many, of the finest capillaries rupture, and innumerable small extravasations of blood, visible to the naked eye as tiny red spots, are deposited into the tissue. In the skin, subcutaneous tissue, and intestinal membranes the process is essentially the same, but to follow it further would lead too far for the present. Let me, therefore, mention another fact. While the blood taken from a vein of a diseased or dead pig invariably contains a large number of spherical bacteria or Micrococci, and very few, and usually small Zoöglœa-masses, the diseased parts of the lungs, and especially the stagnant blood, which oozes out of the capillaries, if the diseased parts of the lungs are cut into small pieces, invariably contains, besides Micrococci, numerous and large Zoöglœa-masses, which are, most of them, much larger than the blood corpuscles, and abundantly large enough to clog the finer capillaries. All this, of course, does not prove that the Schizophytes constitute the cause of the morbid process. I therefore resorted to experiments. Having found that any inoculation of a healthy pig with the fresh pulmonary exudations of a diseased or dead animal invariably produces the disease in three to fifteen days, or on an average in six days, I concluded it might be ascertained in two different ways—in a negative and in a positive way—whether or not the Schizophytes constitute the cause of the morbid process. If it were possible to free the Schizophytes from everything, and to transfer the same without any vehicle whatever from one animal to another, for instance, like a louse or an itch-mite, the question would be very soon answered. But as that cannot be done, I had to get at the facts in a more indirect way. I repeatedly charged two ounces of an innocent fluid, at first pure and fresh milk, then boiled milk, mutton broth, afterwards water, and finally albumen, with one drop of the infectious pulmonary exudation, containing an abundance of Schizophytes. In about three days the fluids thus charged, which, by the way, were kept at a suitable temperature, were found to be swarming with Schizophytes, identical in appearance to those found in the pulmonary exudation; and every inoculation made with these fluids proved to be effective, but in most cases the attack produced was of a comparatively mild type. To go further into particulars would take too much time; I therefore have to refer for particulars to my reports to the Commissioners of Agriculture. One thing, however, I must state. The fluid transferred by each inoculation was less than half a drop, but this half drop contained innumerable Schizophytes, while as far as could be ascertained by careful microscopic examinations, nothing else contained in the original exudation had multiplied. Consequently, nobody, unless he believes in the power of Hahnemannian dilutions, will contradict, and say, the effect of the inoculations is brought about, not by the Schizophytes, but by an unseen and unknown virus, or chemical something, the existence of which cannot be proved. I was, however, not satisfied with these positive results, and concluded to try also the negative way. Knowing that it is impossible to separate the Schizophytes from their vehicle, I tried to free the latter from the Schizophytes, and resorted to filtration. I filtrated the pulmonary exudations through half a dozen of the finest filtering papers obtainable, but found my effort to be in vain, for the filtrate, although freed from the Zoöglœa-masses and rod-shaped bacteria, yet contained numerous Micrococcus-forms. The filtrate was put in a vial with a tight fitting glass-stopper, and when examined three days later, it contained a great many rod-shaped bacteria, and comparatively few Micrococci. I therefore filtered it again with the same result, except that the Micrococcus-forms were not as numerous after the second filtration as after the first. So I filtered the exudation three or four times, each time through four to six filtering papers, and at intervals of about three days till I was finally not able to detect any Micrococci in the now limpid filtrate. Inoculations with this filtrate proved to be ineffective. At another time—in the following winter—I tried again to free pulmonary exudation from the Schizophytes by means of filtration, but did not succeed. The filtrate always — after each filtration — contained numerous Micrococci. Whether, in this second attempt, I did not hit the right time for my second and third filtrations, that is, a time at which most or all of the micrococci had developed to rod-shaped Schizophytes or filaments; whether the temperature was too low—the first, successful attempt was made in the summer—and therefore the development of the Schizophytes was irregular or retarded; whether my filtering papers were not fine enough; or whether all these circumstances combined made the filtration a failure, I do not know. An inoculation made with this filtrate proved to be effective, but the disease produced was of a very mild character; at any rate, the animal recovered.

If more proof is yet required that the Swine-plague-Schizophytes and nothing else constitute the infectious principle of that disease, and it seems that the above facts which have been published more fully in my reports to the Commissioner of Agriculture, are not deemed sufficient, the following facts, if not making it absolutely certain, will at any rate, especially if considered *in toto*, to a great extent, corroborate the assertion that the Schizophytes have, and must have, a causal connection with the morbid process.

1. It has been, and can be, everywhere observed, where Swine-plague is prevailing, that the infectious principle floating in the air, is attracted and taken up by sores, wounds and even scratches, but does not enter the animal organism through the whole skin and through perfectly healthy respiratory mucous membranes.

2. Antiseptics, or medicines, which are either directly poisonous to the lower forms of organic life, or destructive to those conditions, under which low forms of organic life thrive and develop, and among those antiseptics, especially carbolic acid, iodine, hyposulphite of soda, benzoate of soda, thymol, etc., have proved to constitute almost sure prophylactics. As one of the conditions necessary to the development of Swine-plague bacteria, it seems, has to be considered a certain degree of animal heat. At any rate, after, and while the animal heat of a pig is reduced by a continued treatment with carbolic acid, from the normal (102° to 104° F) to an abnormally low temperature (say 96° to 97° F), every innoculation with fresh infectious material has so far proved to remain ineffective. Further, the various antiseptics, which have proved to be good prophylactics, are very dissimilar in their chemical affinities and actions, and their prophylactic effect cannot very well be explained, if the infectious principle were a chemical agency, a virus, or a poison, but is explained, if the same consist in something endowed with life and power of propagation.

3. If the morbid process, the morbid changes effected, particularly the exudations and extravasations of blood on the lungs and in the skin, and the qualitatively unchanged condition of the blood—that is excepting such changes in its composition as are evidently the product, or necessary consequence, of the morbid changes—are taken into consideration, it becomes obvious that something which causes obstructions in the capillary system—embolism—must constitute the cause, and nothing whatever, able to accomplish that result, can be found, except the colonies or clusters of Schizophytes, the Zoöglœa-masses, imbedded in a viscous substance, while on the other hand, these Zoöglœa-masses are never absent in a case of Swine-plague.

If I am allowed to digress a little, it may be here mentioned that I am well aware of the fact that German and French investigators claim for certain, and it may be, for all, kinds of pathogenic Schizophytes chemical actions or fermenting properties, and undoubtedly many of them, especially among those belonging to the genus Bacillus—I mention *B. anthracis*—and probably some others, do possess and exercise such properties, and cause fermentation. As to the Swine-plague Schizophytes, I have not been able to observe any fermenting effect or chemical action, except such as necessarily results from depriving the animal organism of certain elements and material, appropriated by the Schizophytes, and necessary to their subsistence and propagation. All other morbid changes appear to be the consequence of the obstruction of the capillary system by the Zoöglœa-masses, and therefore, are the product of a mechanical, and not of a chemical agency.

4. The adversaries of the so-called "Germ-theory" of diseases, well knowing that a perfect separation of the Schizophytes (Micrococci, Bacteria, or Bacilli, as the case may be) from their vehicles, the animal tissues and fluids, is impossible, demand absolute proof. If conclusions may be drawn from analogy between diseases of animals and plants, Prof. T. J. Burrill,* of the Illinois Industrial University, more favored by the nature of the objects of his investigation (apple-trees, pear-trees and peach-trees) has furnished evidence, amounting to almost absolute proof, that the so-called blight of apple-trees and pear-trees, and the so-called "yellows" of peaches are caused by Schizophytes similar in size, but otherwise not identical to those which I consider as constituting the cause and infectious principle of Swine-plague, as will be seen by consulting the transactions of the meeting of the American Association for the Advancement of Science in Boston, 1880.

If the infectious principle were a chemical poison or virus, its action, one should suppose, would under all circumstances be exactly the same, and the malignancy of the morbid process, and the time required for its development—the so-called period of incubation, or, more correctly, stage of colonization—would not be subject to changes dependent upon the season of the year, upon the individuality and temperature of the animal, and upon other yet unknown external influences, as is undoubtedly the case. An organic poison or virus, one should suppose, would act somewhat like the virus of a poisonous snake. In the same localities, in the same places, or the same yards and pens, and among the same breeds of hogs, in which the disease was exceedingly malignant in 1878; it was, as a rule, much milder in 1879, and still milder in 1880. As such are unmistakable facts, repeatedly and everywhere observed, it must be concluded that nothing but what is able to undergo changes is subject to growth and development, and acquires vigor and propagates rapidly under favorable, but is weakened and multiplies slowly under unfavorable circumstances—in other words, nothing but what is corporeal and endowed with life—can constitute the cause.

* "Science," Vol. I., pp. 162, 191.

6. If the cause and infectious principle of Swine-plague were a chemical poison or virus, one should suppose a cessation of the morbid process would be impossible, and an animal would never recover, while its organism contains an abundance of the infectious principle in an effective condition, as is undoubtedly the case, because convalescents, and animals nearly recovered, frequently communicate the disease, even in a fatal form, to other, healthy pigs. Further, the fact that an animal, once recovered, possesses but little predisposition for future infection, or is seldom attacked a second time, even if ever so much exposed, and then only contracts the disease in a comparatively mild form, could never be explained; but the whole presents an entirely different aspect, and admits explanation, if low and minute forms of organic life, such as the Schizophytes of Swine-plague, which, by developing and multiplying, finally destroy or exhaust in an animal organism the conditions necessary to future development and propagation, constitute the cause and the infectious principle. (cf. an article entitled: "*The Destruction of Germs*," in "*Popular Science Monthly*," communicated in extract in *R. Hitchcock's Microscopical Journal*, Nov., 1880.)

7. If some part or organ of a pig infected with Swine-plague happens to be in a state of congestion, such a part invariably attracts the infectious principle, and becomes a prominent, if not the principal, seat of the morbid process; a fact difficult of explanation, unless the infectious principal is something solid or corporeal.

8. The adversaries of the so-called "Germ Theory," as they are pleased to call it, demand absolute proof of those who claim that certain infectious diseases owe their origin, or existence and spreading, to very minute forms of organic life. They cannot deny that these forms exist, can be found, and have been shown, but forget to show their virus, poison, fluidum, or chemical something. Does the latter exist only in their imagination? If the adversaries of the so-called "Germ Theory" demand absolute proof on our side of the question, let them set a good example and furnish it on their side, or only produce their virus, fluidum, or whatever it may be, and we will gracefully acknowledge that we are mistaken, and have labored in vain.

9. With the very best objectives ever made, and a fair ability to handle the microscope, I have never been able to find anything identical to the Swine-plague Schizophytes in the blood and tissues of other healthy animals. When I commenced my investigation, the best objective at my disposal was a very fair 1–9 four system immersion lens of Hartnack & Prazmowski, but I soon found it to be insufficient, and procured a 1–16 immersion of the same makers. This, too, after a while, did not give satisfaction, and I received a 1–12 (nominally 1–10) glycerine immersion of R. B. Tolles, which that renowned maker afterwards exchanged for a duplex 1–10 homogeneous immersion. This latter objective proved to be a very superior lens, and gave me glimpses of things of which I desired to see a little more—it showed flagella on *Bacillus subtiles*, which I had never seen with any of the other objectives—and so I thought with a higher power, and a still more perfectly corrected lens, if a more perfect correction could be made, I might be able to see more plainly the distinguishing forms and characteristics of the Swine-plague Schizophytes, and also learn a little more about their mode and manner of propagation. I therefore asked Mr. Tolles to make me a higher power objective especially adapted to my work, and he has furnished me a duplex 1–15 homogeneous immersion objective (in reality a little more than a 1–16), which is, beyond comparison, the best objective I have ever seen. It is even superior, in definition and flatness of field, to a magnificent 1–18 homogeneous immersion objective (in reality a 1–20) of Carl Zeiss, made to order a month or two ago.

As to a proper generic place and name of these Swine-plague Schizophytes, I am at a loss. The best authorities—

Cohn, Klebs, and others—who have attempted a classification are somewhat undecided themselves, and do not agree where generic lines ought to be drawn. At any rate, the Swine-plague Schizophytes do not fit into any of the genera proposed. They are not bacteria, because the single cells are spherical and not oblong; they can hardly be considered as Micrococci, because the same are bi-spherical in their advanced stage of development; and they cannot be classed among the Bacilli on account of their forming Zoöglœa-masses. I have, therefore, preferred to use, for the present, that name, which, without any serious contradiction, is given by modern investigators to the whole family: Schizophytæ or Schizophytes, or the older name, introduced by Naegeli, Schizomycetes.

The Swine-plague Schizophytes present themselves, according to their stage of development, in three different forms and shapes. Their simplest form, it seems, is that of a Micrococcus, or of a small globule of about 0.7 or 0.8 microm. ($\frac{1}{33500}$ inch) in diameter. It occurs invariably in the blood, the morbid products, and exudations, etc. of the diseased animals, and is never absent, but can always be found, though in some cases in much greater numbers than in others. The second form is bi-spherical – the spherical cell having duplicated itself by a gradual contraction in the middle, while growing endwise. These bi-spherical Schizophytes are always more or less numerous, and are motile, or move about, provided the temperature of their vehicle—lung-exudation or blood-serum, for instance—is not too low. Some of them, but probably only those, which, separated from a larger chain, as will presently be explained, are provided, at any rate at one end, with a flagellum—a post-flagellum—which, however, is so exceedingly fine that it can be seen only with the very best high-power objectives, like a Tolles 1–15, and the most favorable light obtainable, and even then only while the Schizophyte is slowly moving. I have never yet been able to see it while the Schizophyte is at rest.

These double Micrococci, or bi-spherical Schizophytes, soon undergo further development. Each single cell soon again contracts in the middle while growing endwise, and, at the same time, separates more and more, and becomes partially independent from its sister cell, with which, however, it remains connected for some time, even after it has completed its duplication. Meanwhile the sister-cell, too, has become bi-spherical, and what a short while ago was a simple bi-spherical cell, has become a double bi-spherical body, resembling a small chain of four round joints. But the duplication does not stop; each of the four single cells, within a short time, doubles again, and soon quite a little rod or filament will be formed, which, on close inspection, presents a string or chain of bi-spherical cells endways, loosely connected with each other. Under moderately high powers—say of 800 or 900 diameters—such a string presents a slender, rod-shaped moniliform bacterium. While the single cells, or each half of each bi-spherical body, soon develop into double or bi-spherical cells, the connection between the latter gradually loosens, so that finally, if the temperature is not too low, and the development a rapid one—I have frequently observed that the number of bi-spherical cells in such a chain becomes doubled in less than five minutes—the chain breaks up into smaller ones (joints), each consisting of one or two bi-spherical Schizophytes, which, in separating from their neighbors, after some swinging to and fro, spin or draw out a very slender thread, a flagellum or cilium. But before all these changes, this rapid duplication, take place, the spherical Micrococci, when about to change to bi-spherical bodies, form those clusters (Zoöglœa or Coccoglia masses), which, being imbedded in, or kept together by, an apparently viscous substance, obstruct the capillaries, and, according to my observations, constitute the principal and direct cause of the morbid process. In these Zoöglœa-masses the single Micrococci, it seems, undergo their first metamorphosis, or change to double bi-spherical cells, and this change continues, till portions of the Zoöglœa-mass separate, or till finally the glia breaks and opens, when the bi-spherical bodies, and also some yet unchanged spherical Micrococci, become free. The former, very soon, commence their duplication, but as each new cell or globule soon produces another one and becomes bi-spherical, the same cannot be the source of the spheriral bodies or Micrococci. The latter, it appears, have another origin, as will be presently explained.

In Swine-plague material, such as blood, blood-serum, lung-exudation, etc., if a day or two old, and sometimes while yet fresh, bacteria of a peculiar shape and form make their appearance. The same are rod-shaped, and a trifle longer than a bi-spherical Schizophyte, or two united spherical bodies, but are not moniliform, and have at one end, or in comparatively rare cases toward the middle, a bright and light-refracting globule of much more density than the rest of the bacterium. This globule is surrounded by a substance or an envelope of considerably less density and is therefore less light-refracting. If that globule is situated at one end of the bacterium as is usually the case, the whole bacterium presents the shape of a club, because the globule and its envelope have much more diameter than the rod. Billroth calls this form a Helobacterium, and the globule a lasting spore (Dauerspore). Such a lasting spore, according to Billroth and Cohn, at any rate, if developed by a Bacillus, is able to resist very high degrees of heat and cold, and is very prolific, as it disseminates a large number of germs, which, probably, constitute the source of the globular bacteria or Micrococci. As such Helobacteria are often found in perfectly fresh blood, and exudations, etc. (in the exudations most frequently) of hogs, which are affected with, or have died of Swine-plague, and are nearly always seen if the blood and exudations, etc., are a few days old, it appears probable that the same not only constitute the source of the spherical bacteria or Micrococci, but also that their great tenacity of life, or resistibility against adverse external influences, explains the ability of the infectious principle of Swine-plague to remain effective for a whole year, if protected, by clinging to, or being imbedded, in a moist and porous substance, such as an old straw stack, etc.

Whether or not Swine-plague-Schizophytes are able to multiply in any other form and manner than stated, I have not been able to observe. One observation, made already at the beginning, has found new and repeated confirmation, viz: wherever, or as soon as *Bacterium termo* makes its appearance in large numbers, the Swine-plague Schizophytes commence to disappear and disappear in about the same ratio, in which the former are increasing in numbers. In blood kept in a vial, Swine-plague Schizophytes cannot be found when the blood commences to exhibit a purplish color, or when the blood corpuscles commence to decay, or become destroyed. Further, the Swine-plague Schizophytes, although presenting the same general characteristics when cultivated in fluids foreign to the animal organism of a hog, show differences in so far as the same present less uniformity in size, and as this development and multiplication proceed slower, and with much less regularity. It seems the cultivated Schizophytes change and develop slower, and probably on that account are less vigorous in producing mischief—at any rate, an inoculation with cultivated Swine-plague Schizophytes, although effective in producing the disease, is always followed by a comparatively milder form of Swine-plague than an inoculation with material directly from the body of a diseased hog. This, however, does not involve that every inoculation with cultivated Schizophytes produces under all circumstances a milder form of Swine-plague, than any natural infection, for such is not the case. The difference may be stated thus: A natural infection, or an inoculation with material directly from the body of a diseased hog, as a rule, produces a malignant and dangerous attack

and as an exception a mild form of the disease—the frequency of the exception depending, it seems, to a great extent upon the prevailing character of the plague, while an inoculation with the cultivated Schizophytes is, as a rule, followed by a mild attack, and as an exception, or in rare cases only, by Swine-plague in its severest form.

Wherever Swine-plague is prevailing in its most malignant or fatal form, or, what is essentially the same, wherever formation of ulcerous tumors in the cæcum and colon is a frequent occurrence, where consequently an abundance of Swine-plague Schizophytes is discharged with the excrements of the diseased animals, there the spreading from animal to animal, and from herd to herd, is a rapid one; and *vice versa*, wherever the spreading is rapid, there ulcerous tumors in the intestines are a frequent occurrence. In 1878 the same (the ulcerous tumors) could be found in about 75 per cent. of all cases that had a fatal termination, while at present (in Illinois) their occurrence is probably limited to about 5 per cent. of all cases.

THE KANSAS CITY ELECTRIC TIME BALL.

By Prof. H. S. PRITCHETT, Astronomer at Morrison Observatory, Glasgow, Missouri.

The first time ball established in the United States was dropped from the dome of the Naval Observatory at Washington in 1855. It is still dropped at Washington mean noon, and has for a long time furnished the standard time for the city and the Departments of the Government.

The New York time ball, established in 1877, is dropped at New York noon, by an electric signal, sent from the Naval Observatory at Washington. It was erected and is maintained by the Western Union Telegraph Company, and is dropped from their building on Broadway. At 11h. 55m. the ball is hoisted half-way up the staff on the tower of the building. At 11h. 58m. it is hoisted to its highest point, when it is about 250 feet above the street and can be well seen by the shipping at the New York and Brooklyn docks, and vessels in the bay, and from suitable positions is visible to a large part of the citizens of New York, Brooklyn, Hoboken and Jersey City.

If on account of wind the ball fails to drop at 12h. om. os., it is held till 12h. 5m. and then dropped. In such cases a small red flag is hoisted at 12h. 1m. and kept flying till 12h. 10m. This ball was for some time dropped by hand, but for the last year the dropping has been automatically effected by the clock at the Observatory. The working of the apparatus has been in the main satisfactory, and the ball has been dropped quite regularly, the failures being caused almost entirely by temporary breaks in the wire or other causes which could not be foreseen.

In the evening papers of the day and in the papers of the next morning a notice is regularly inserted, stating whether the ball dropped at correct time, and if not, its error, fast or slow. Many are at a loss to know how this correction is obtained. It is arrived at in the following manner: The time of the falling of the ball records itself automatically by electricity, near the standard clock of the Western Union Company in the building, the clock itself being regulated by the daily clock-signals from Washington. The difference between the time of falling of the ball and noon, as indicated by the clock, is thus obtained by a direct comparison. This assumes of course the accuracy of the clock, and during a long continued season of cloudy weather, or in case of accident to the clock itself, the time might be somewhat in error, although the published correction might show but a few hundreths of a second. At present however, the Western Union has the benefit also of the Alleghany and Cambridge signals, for the regulation of this clock, so that even during the longest season of cloudy weather it is not probable that the clock could be much in error.

The Boston time ball, which is dropped at noon of Boston time, by means of the noon-time signal from the standard clock of the Harvard College Observatory, is placed upon the large building of the Equitable Life Assurance Company and was paid for and is now maintained by this company. The ball is of copper and weighs about 250 pounds. The machinery used in raising and controlling it is hence much more complicated and costly than in either of the cases before mentioned. The cost of ball and machinery was about $1200. The electric signal which drops it, is given by the clock itself, the ball having a drop of fifteen feet. The nearness of the Observatory, and the fact that the wire used is wholly under its control, give additional convenience and certainty in the dropping of the ball, and reduces the probability of accidents to a minimum, so that it is effected with great regularity and precision. Prof. Pickering, Director of the Observatory, reports for the year ending Nov. 1st, 1880, the ball was dropped exactly at noon on 355 days; on four other days at five minutes past noon, in accordance with the rule adopted; on four other days it was not dropped, leaving only three cases of inaccuracy of dropping.

Quite recently a time ball has been established at Hartford, Conn., and dropped by the Winchester Observatory of Yale College.

The time ball recently erected at Kansas City, and which is dropped as a part of the time service of the Morrison Observatory, is the first attempt in this direction in the West. It was paid for chiefly by an appropriation of the City Council of that city. The site selected was the large building just erected by the Messrs. Bullene, Moores & Emery, on Delaware street. The ball when raised to the top of the staff is about 140 feet above the street, and is generally visible to the business portion of the city. The ball which passes over the staff, is simply a wire skeleton covered with canvas and painted black, and is about three feet in diameter. It was loaded on the inside with lead until it was found to drop instantly and without loss of time. It has a drop of about twenty-five feet and is slowed up as it reachcs the bottom, and is received upon a set of tall springs surmounted by a stout cushion.

The apparatus by means of which the ball is dropped at precisely the right instant, was constructed under the direction of Mr. W. F. Gardner, the instrument maker of the Naval Observatory at Washington, It is of a very simple form, and is found to answer all requirements.

This has been found to work easily and without loss of time and can scarcely get out of order. The entire cost of mounting the ball and machinery was only about $120, and with this small amount it was necessary to use the utmost economy in the purchase of materials and apparatus. Kansas City is about one hundred miles from the Observatory, and except in cases of breaking of the wire, when the ball cannot be dropped at all, it is dropped within one or two-tenths of a second of correct time.

The discrepancy in the local time kept by different jewelers in the city before the erection of the ball was astonishing, and led to endless confusion in business and travel.

On the first day the ball dropped, this difference, in extreme cases, amounted to fifteen or twenty minutes, some being eight or ten minutes fast, others as slow. The establishment of the time ball has brought about a uniformity never before known, and must soon make itself felt, not only as a convenience, but a promoter of punctuality in business engagements.

From the daily clock-signals sent over the wires from the Observatory it will be easy to establish a similar time signal in any city in the West, which will take the

necessary steps to procure these signals. An arrangement has been made also by which they may be distributed to jewelers and clockmakers, and manufacturing establishments in the larger cities.

THE UNITY OF NATURE.

By the Duke of Argyll.

VII.

ON THE MORAL CHARACTER OF MAN CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

(*Continued*).

Of one thing, at least, we may be tolerably certain respecting the causes which have led to this extreme dispersion of Mankind to inhospitable regions, at a vast distance from any possible center of their birth. The first Fuegian was not impelled to Cape Horn by the same motives which impelled Mr. Darwin to visit that country in the *Beagle*. The first Eskimo, who wintered on the shores of Baffin's Bay, was not induced to do so for the same reasons which led to the expeditions of Back, of Franklin, or of Rae. The first inhabitants of Australasia did not voyage there under conditions similar to those which attended the voyages of Tasman or of Cook. We cannot suppose that those distant shores were first colonized by men possessed with the genius, and far advanced in the triumphs, of modern civilization. Still less can we suppose that they went there under the influence of that last development of Man's intellectual nature, which leads him to endure almost any suffering in the cause of purely scientific investigation.

Nor is this the only solution of the difficulty which seems to be absolutely excluded by the circumstances of the case. Within the historical period, and in the dim centuries which lie immediately beyond it, we know that many lands have been occupied by conquering races coming from a distance. Sometimes they came to subdue tribes which had long preceded them in occupation, but which were ruder, as well as weaker, than themselves. Sometimes, as in the case of the northern nations bursting in upon the Roman empire, they came to overthrow a civilization which had once been, and in many ways still was, much higher than their own, but which the progress of development in a wrong direction had sunk in degradation and decay. Sometimes they came simply to colonize new lands, at least as favored, and generally much more favored, than their own—bringing with them all the resources of which they were possessed—their flocks and herds, their women and children, as well as their warriors with chariots and horses. Such was the case with some of those nations which at various times have held their sway from Central Asia into Eastern and Central Europe. They were nations on the march. But no movement of a like kind has taken place for many centuries. Lastly, we have the emigrations of our own day, when civilized men, carrying with them all the knowledge, all the requirements, and all the materials of an advanced civilization, have landed in countries which by means of these could be made fit for settlement, and could be converted into the seats of agriculture and of commerce.

Not one of these cases can reasonably be supposed to have been the case of the first arrival of Man in Australasia. The natural disadvantages of the country, as compared with the richness and abundance of the regions from which he must have come, or which were on his southward line of march, preclude the supposition that men were attracted to it by natural objects of desire. We know by experience that if the first settlers had been in a condition to bring with them the higher animals which abound in Asia, these animals would have flourished in Australia as they now do. And so, also, with reference to the cereals—if these had ever been introduced, the modern Australians would not have been wholly without them, and would not have been compelled to live so much on the lowest kinds of animal and vegetable food—on fish, lizards, grubs, snakes, and the roots of ferns.

There is, however, one answer to Mr. Darwin's question, which satisfies all the conditions of the case. There is one explanation, and only one, of the dispersion of the human race to the uttermost extremities of the habitable globe. The secret lies in that great law which Malthus was the first to observe and to establish—the law, namely, that population is always pressing on the limits of subsistence. There is a constant tendency to multiplication beyond those limits. And, among the many consequences of this tendency, the necessity of dispersion stands first and foremost. It is true, indeed, that under some conditions, such as those which have been already indicated, the most energetic races, or the most energetic individuals, have been those who moved. But under many other conditions the advantage has been in favor of those who staid. Quarrels and wars between tribe and tribe, induced by the mere increase of numbers, and by consequent pressure upon the means of living, have been always, ever since Man existed, driving the weaker individuals and the weaker families farther and farther from the original settlements of Mankind.

Then one great argument remains. In the nature of things the original settlements of Man must of necessity have been the most highly favored in the conditions he requires. If, on the commonly received theory of Development, those conditions produced him, they must have reached at the time when, and in the place where, he arose, the very highest degree of perfect adaptation. He must have been happy in the circumstances in which he found himself placed, and presumably he must have been contented to remain there. Equally on the theory of Man being a special creation, we must suppose that when weakest and most ignorant he must have been placed in what was to him a garden—that is to say, in some region where the fruits of the earth were abundant and easily accessible. Whether this region were wide or narrow, he would not naturally leave it except from necessity. On every possible supposition, therefore, as to the origin of Man, those who in the dispersion of the race were first subjected to hard and unfavorable conditions would naturally be those who had least strength to meet them, and upon whom they would have accordingly the most depressing effect. This is a process of Natural Rejection which is the inseparable correlative of the process of Natural Selection. It tends to development in a wrong direction by the combined action of two different circumstances which are inherent in the nature of the case. First, it must be always the weaker men who are driven out from comfortable homes; and, secondly, it must be always to comparativly unfavorable regions that they are compelled to fly. Under the operation of causes so combined as these, it would be strange, indeed, if the physical and mental condition of the tribes which have been exposed to them should remain unchanged. It is true, indeed, that adverse conditions, if they be not too severe, may develop energy, and result in the establishment of races of special hardihood. And in many cases this has been the actual result. But, on the other hand, if physical conditions be as insuperable as those which prevail in Tierra del Fuego or in Baffin's Bay; or if, though less severe than these, they are nevertheless too hard to be overcome by the resources at the disposal of the men who are driven to encounter them, then the battle of life becomes a losing one. Under such circumstances, degration is unavoidable. As surely as the progress of Man is the result of opportunity, that is to say, as surely as it is due to the working of his faculties under stimulating and favoring conditions, so surely must he descend in the scale of intelligence and culture, when that opportunity is taken from him, and when these faculties are placed under conditions where they have no call to work.

It is, then, easy to see some at least of the external circumstances, which, first, in the natural course of things,

would bring an adverse influence to bear upon Mankind. Here we are on firm ground, because we know the law from which comes the necessity of migrations, and the force which has propelled successive generations of men farther and farther in ever widening circles round the original centre or centres of their birth. Then, as it would be always the feebler tribes which would be driven from the ground which has become overstocked, and as the lands to which they went forth were less and less hospitable in climate and productions, the struggle for life would be alwaye harder. And so it would generally happen, in the natural course of things, that the races which were driven farthest would become the rudest and the most engrossed in the pursuits of mere animal existence.

Accordingly, we find that this key of principle fits into and explains many of those facts in the distribution and condition of Mankind, which, in the case of the Fuegians, excited the wonder and curiosity of Darwin. In the light of this explanation, these facts seem to take form and order. It is a fact that the lowest and rudest tribes in the population of the globe have been found, as we have seen, at the farthest extremities of its larger continents—or in the distant islands of its great oceans, or among the hills and forests which in every land have been the last refuge of the victims of violence and misfortune. These extreme points of land which in both hemispheres extend into severe latitudes are not the only portions of the globe which are highly unfavorable to man. There are other regions quite as bad, if not, in some respects, even worse. In the dense, uniform and gloomy forests of the Amazon and Orinoco there are tribes which seem to be among the lowest in the world. It cannot be unconnected with the savagery of the condition to which they have been reduced that we find the remarkable fact that all those regions of Tropical America are wholly wanting in the animals which are capable of domestication; and which are inseparable from the earliest traces of human culture. The Ox, the Horse, and the Sheep are all absent—even as regards the genera to which they belong. There are indeed the Tapir, the Paca, and the Curassow Turkey, and all these are animals which can be tamed. But none of them will breed in confinement, and the races cannot be established as useful servants of Mankind. In contrast with these and with other insuperable disadvantages of men driven into the forests of Tropical America, it is instructive to observe that the same races, where free from these disadvantages, were never reduced to the same condition. In Peru the Indian races had the Llama, and had also an advanced civilization.[4] In India, too, it is always the Hill Tribes who furnish the least favorable specimens of our race. But in every one of these cases we have the presence of external circumstances and physical conditions which are comparatively unfavorable. It is quite certain that these conditions must have had their own effect. It is equally certain that the races which have been subject to them for a long and indefinite time must have been once under the influence of conditions much more favorable; and the inevitable conclusion follows, that the savagery and degradation of their existing state is to a great extent the result of development in a wrong direction.

There are other arguments all pointing the same way, the force of which cannot be fully estimated, except by those who are familiar with some of the fundamental conceptions which seem to rise unbidden in the mind from the facts which geology has revealed touching the history of Creation. One of these facts is that each new organic Form, or each new variety of birth, seems to have been introduced with a wonderful energy of life. It is needless to repeat that this fact stands in close connection with every possible theory of Evolution. If these new Forms were the product of favoring conditions, the prevalence of these conditions would start them with force upon their way. The initial energy would be great. Where every condition was favorable—so favorable indeed that the new birth is assumed to have been nothing but their natural result—then the newly-born would be strong and lusty. And such, accordingly, is the fact in that record of creation which Palæontology affords. The vigor which prevails in the youth of an individual is but the type of the vigor which has always prevailed in new and rising species. All the complex influences which led to their being born, led also to their being fat and flourishing. That which caused them to arise at all must have had the effect of causing them to prevail. The condition of all the lowest races of men is in absolute contrast with everything which this law demands. Everywhere, and in everything, they exhibit all the characteristics of an energy which is spent —of a force which has declined—of a vitality which has been arrested. In numbers they are stationary, or dwindling; in mind they are feeble and uninventive; in habits they are stupid or positively suicidal.

It is another symptom of a wrong development being the real secret of their condition that the lowest of them seem to have lost even the power to rise. Though individually capable of learning what civilized men have taught them, yet as races they have been invariably scorched by the light of civilization, and have withered before it like a plant whose roots have failed. The power of assimilation seems to have departed, as it always does depart, from an organism which is worn out. This has not been the result with races which, though very barbarous, have never sunk below the pastoral or the agricultural stage. It is remarkable that the Indian races of North America are perhaps the highest which have exhibited this fatal and irredeemable incapacity to rise; and it is precisely in their case that we have the most direct evidence of degradation by development in a wrong direction. There are abundant remains of a very ancient American civilization, which was marked by the construction of great public works and by the development of an indigenous agriculture founded on the maize, which is a cereal indigenous to the continent of America. This civilization was subsequently destroyed or lost, and then succeeded a period in which Man relapsed into partial barbarism. The spots which had been first forest, then, perhaps, sacred monuments, and thirdly, cultivated ground, relapsed into forest once more.[5] So strong is this evidence of degradation having affected the population of a great part of the American continent, that the distinguished author from whom these words are quoted, and who generally represents the savage as the nearest living representative of primeval man, is obliged to ask, "What fatal cause destroyed this earlier civilization? Why were these fortifications forsaken—these cities in ruins? How were the populous nations which once inhabited the rich American valleys reduced to the poor tribes of savages whom the European found there? Did the North and South once before rise up in arms against one another? Did the terrible appellation, the 'Dark and Bloody Land,' applied to Kentucky, commemorate these ancient wars?"[6] Whatever may have been the original cause, the process of degradation has been going on within the historic period. When Europeans first came in contact with the Indian tribes, there was more agriculture among them then than there is now. They have long descended to the condition of pure hunters. The most fundamental of all the elements of a civilized and settled life—the love and practice of agriculture—has been lost. Development in the wrong direction had done its work. There is no insoluble mystery in this result. It is, in all probability, if indeed it be not certainly,

[4] "Naturalist on the Amazons," Bates, vol. i. p. 191–3.

[6] *Ibid.*, p. 236.

attributable to one cause, that of internecine and devastating wars. And these again are the result of a natural and universal instinct which has its own legitimate fields of operation, but which like all other human instincts is liable to degenerate into a destructive passion. The love of dominion is strong in all men, and it has ever been strongest in the strongest races. But the love of fighting and of conquest very often does sink into a mere lust of blood. The natural rivalry of different communities may become such implacable hatred as to be satisfied with nothing short of the extermination of an enemy. Inspired by this passion, particular races or tribes have sometimes acquired a power and a ferocity in fighting, against which other tribes of a much higher character and of a much more advanced civilization have been unable to contend.

This is no fancy picture. It is a mistake to suppose that the decline of civilization in the American continent has been due to the invasion of it by Europeans since the discovery of Columbus. Just as the older civilization of that continent was an indigenous civilization founded on the cultivation of a cereal peculiar to the American continent, so also does the decay and loss of this civilization seem to have been a purely indigenous decay. Mr. Wilson, in his very interesting work on "Prehistoric Man," gives an account of the process by which barbarism has been actually seen extending among the Red Indian tribes. When the valley of the St. Lawrence first came under the observation of Europeans, some of those tribes were found to be leading a settled life, practicing agriculture, and constituting communities in possession of all the elements of a civilization fairly begun, or probably long inherited. The destruction of these communities was affected by the savage hostility of one or two particular tribes, such as the Iroquois and the Mohawks. In these tribes the lust of blood had been developed into an absorbing passion, so that their very name became a terror and a scourge, Wholly given up to war as a pursuit, their path was red with blood, and the more peaceful and civilized branches of the same stock were driven, a scanty remnant, into forests and marshes, where their condition was necessarily reduced to that of savages, living wholly by the chase. It is a curious and instructive fact that this sequence of events was so vividly and painfully remembered among some of the Red Indian tribes that it had become embodied in a religious myth. It was said that in old times the Indians were increasing so fast that they were threatened with want, and that the Great Spirit then taught them to make war, and thus to thin one another's numbers.[7] Although this myth stands in very close connection with the universal tradition of a Golden Age, or of a Past in some measure better than the Present, it is remarkable on account of the specific cause which it assigns for deterioration and decay, a cause in respect to which we have historical evidence of its actual effect. When the great French navigator, Cartier, first explored the St. Lawrence in 1534–5, he ascended to that point of its course whence the city of Montreal now looks down upon its vast and splendid prospect of fertile lands and of rushing waters. He found it occupied by the Indian town of Hochelaga—inhabited by a comparatively civilized people, busy not only in fishing or in hunting, but also in a successful husbandry. The town was strongly fortified, and it was surrounded by cultivated ground. Within one hundred and seven years—some time between 1535 and 1642—Hochelaga had utterly disappeared, with all its population, and all its culture. It had been destroyed by wars, and its site had returned to forest or to bush. To this day when men dig the foundations of new houses in Montreal they dig up the flint implements of the Hochelagans, which, although about 350 years old, may now be reckoned by the scientific anthropologist as relics of the "Stone Age,"[8] and of an ancient universal savagery. The same course of things prevailed over the greater part of Canada. During the first half of the seventeenth century a large part of the valley of the St. Lawrence, and vast tracts of country on both shores of the great Lakes, are known to have been devastated by exterminating wars. In 1626 a Jesuit missionary penetrated into the settlement of a tribe called the Attiwenderonks. He found them inhabiting towns and villages, and largely cultivating tobacco, maize and beans. The country inhabited by the tribe which has left its name in Lake Erie, is stated to have been greatly more extensive, and is everywhere covered with the marks of a similar stage of civilization. Within less than thirty years another missionary found the whole of these regions a silent desert. In like manner the country round Lake Huron was, at the same period of time, seen to be full of populous villages defended by walls, and surrounded by cultivated fields. But the same fate befell them.[9] They were extirpated by the Mohawks.

Here then we see in actual operation, within very recent times, a true cause—which is quite capable of producing the effects which, by some means or another, have certainly been produced—and that, too, on the largest scale—upon the American continent. It is a cause arising out of one of the universal instincts of Mankind, developed in such excess as to become a destructive mania. Many nations most highly civilized have been extremely warlike—and the ambition they have cherished of subduing other nations has been the means of extending over the world their own knowledge of the arts of government, and their own high attainments in the science of jurisprudence. But when the same passion takes possession of ruder men, and is directed by irrational antipathies between rival families and rival tribes, it may be, and has often been one of the most desolating scourges of humanity. In itself an abuse and a degradation which none of the lower animals exhibit, it tends always to the evolution of further evils, to the complete destruction of civilized communities or to the reduction of their scanty remnants to the condition and the habits of savage life.

It results from these facts and considerations, gathered over a wide field of observation and experience, that the processes of Evolution and Development as they work in Man, lead to consequences wholly different from those to which they lead in other departments of Creation. There, they tend always in one of two directions, both of which are directions predetermined and in perfect harmony with the unity of Nature. One of these directions is that of perfect success, the other of these directions is that of speedy extinction. Among the lower animals, when a new Form appears, it suits exactly its surrounding conditions; and when it ceases to do so it ceases to survive. Or if it does survive it lives by change, by giving birth to something new, and by ceasing to be identical with its former self. So far as we can actually see the past work of development among the beasts, it is a work which has always led either to rapid multiplication or to rapid extinction, There is no alternative. But in man the processes of Evolution lead in a great variety of directions—some of them tending more or less directly to the elevation of the creature, but others of them tending very speedily and very powerfully to its degradation. In some men they have led to an intellectual and moral standing, of which we can conceive it to be true that it is only a "little lower than the angels." In others they have ended in a condition of which it is too evidently true that it is a great deal lower than the condition of beasts.

We can get, however, a great deal nearer towards the understanding of this anomaly than the mere recognition of it as a fact. Hitherto we have been dealing only with

one of the two great causes of change,—namely, that of unfavorable external or physical conditions. Let us now look at the other—namely, the internal nature and character of Man. We can see how it is that, when working under certain conditions, the peculiar powers of Man must lead to endless developments in a wrong direction. Foremost among these powers is the gift of Reason. I speak here of Reason not as the word is often used, to express a great variety of powers, but as applied to the logical faculty alone. In this restricted sense, the gift of Reason is nothing more than the gift of seeing the necessity or the natural consequences of things—whether these be things said or things done. It is the faculty by which, consciously or unconsciously, we go through the mental process expressed in the word "therefore." It is the faculty which confers on us a true gift of prophecy—the power of foreseeing that which "must shortly come to pass." In its practical application to conduct, and to the affairs of life, it is the gift by which we see the means which will secure for us certain ends, whether these ends be the getting of that which we desire, or the avoiding of that which we dread. But in its root, and in its essence, as well as in its application to the abstract reasoning of mathematics, it is simply the faculty by which we see one proposition as involving, or as following from another. The power of such a faculty obviously must be, as it actually is, immeasurable and inexhaustible, because there is no limit to this kind of following. That is to say, there is no end to the number of things which are the consequence of each other. Whatever happens in the world is the result of causes, moral or material, which have gone before, and this result again becomes the cause of other consequences, moral or material, which must follow in their turn. It is a necessary result of the unity of nature, and of the continuity of things, that the links of consequence are the links of an endless chain. It is the business of Reason to see these links as they come one by one gradually into view; and it is in the nature of a reasoning creature to be drawn along by them in the line, whatever it may be, which is the line of their direction. The distance which may be traversed in following that direction even for a short time, and by a single mind, is often very great—so great that a man may be, and often is, a different Being from himself, both in opinions and in conduct, at two different epochs of his life. There are, indeed, individuals, and there are times and conditions of society, in which thought is comparatively stagnant, when it travels nowhere, or when its movements are so slow and gradual as to be imperceptible. But, on the other hand, there are times when mind is on the march. And then it travels fast and far. The journey is immense indeed, which may be accomplished by a few successive generations of men following, one after another, the links of consequence. At the end of such a journey, the children may be separated from their fathers by more than the breadth of oceans. They may have passed into new regions of thought and of opinion, of habit and of worship. If the movement has been slow, and if the time occupied has been long, it will be all the more difficult to retrace the steps by which the change has been brought about. It will appear more absolute and complete than it really is—the new regions of thought being in truth connected with the old by a well-beaten and continuous track.

But these endless processes of development arising out of the operation of the reasoning faculty, are consistent with any result—good or bad. Whether the great changes they produce have been for the better or for the worse, must depend, not on the length of the journey, but on the original direction in which it was begun. It depends on whether that direction has been right or wrong—on whether the road taken has been the logical development of a lie. The one has a train of consequences as long and as endless as the other. It is the nature of the reasoning faculty that it works from data. But these data are supplied to it from many different sources. In the processes of reasoning on which the abstract sciences depend, the fundamental data are axioms or self-evident propositions. These may, in a sense, be said to be supplied by the reasoning faculty itself, because the recognition of a truth as self-evident is in itself an exercise of the reasoning faculty. But in all branches of knowledge, other than the abstract sciences, that is to say, in every department of thought which most nearly concerns our conduct and our beliefs, the data on which Reason has to work are supplied to it from sources external to itself. In matters of Belief, they come, for the most part, from Authority, in some one or other of its many forms, or from imagination working according to its own laws upon impressions received from the external world. In matters of conduct, the data supplied to Reason come from all the innumerable motives which are founded on the desires. But in all these different provinces of thought it is the tendency and the work of Reason to follow the proposition, or the belief, or the motive, to all its consequences. Unless, therefore, the proposition is really as true as it seems to be; unless the belief is really according to the fact; unless the motive is really legitimate and good, it is the necessary effect of the logical faculty to carry men farther and farther into the paths of error, until it lands them in depths of degradation and corruption of which unreasoning creatures are incapable. It is astonishing how reasonable—that is to say, how logical—are even the most revolting practices connected, for example, with religious worship or religious customs, provided we accept as true some fundamental conception of which they are the natural result. If it be true that the God we worship is a Being who delights in suffering, and takes pleasure, as it were, in the very smell of blood, then it is not irrational to appease Him with hecatombs of human victims. This is an extreme case. There are, however, such cases, as we know, actually existing in the world. But, short of this, the same principle is illustrated in innumerable cases, where cruel and apparently irrational customs are in reality nothing but the logical consequences of some fundamental belief respecting the nature, the character, and the commands of God. In like manner, in the region of morals and of conduct not directly connected with religious beliefs, Reason may be nothing but the servant of Desire, and in this service may have no other work to do than that of devising means to the most wicked ends. If the doctrine given to Reason be the doctrine that pleasure and self-indulgence, at whatever sacrifice to others, are the great aims and ends of life, then Reason will be busy in seeking out "many inventions" for the attainment of them, each invention being more advanced than another in its defiance of all obligation and in its abandonment of all sense of duty. Thus the development of selfishness under the guidance of faculties which place at its command the great powers of foresight and contrivance, is a kind of development quite as natural and quite as common as that which constitutes the growth of knowledge and of virtue. It is indeed a development which, under the condition supposed—that is to say, the condition of false or erroneous data supplied to the reasoning faculty—is not an accident or a contingency, but a necessary and inevitable result.

And here there is one very curious circumstance to be observed, which brings us still closer to the real seat of the anomaly which makes Man in so many ways the one great exception to the order of Nature. That circumstance is the helplessness of mere Reason to correct the kind of error which is most powerful in vitiating conduct. In those processes of abstract Reason which are the great instruments of work in the exact sciences, the reasoning faculty has the power of very soon detecting any element of error in the data from which it starts. That any given proposition leads to an absurd result is one of the familiar methods of disproof in mathematics.

That one of only two alternatives is proved to be absurd is conclusive demonstration that the other must be true. In this way Reason corrects her own operations, for the faculty which recognizes one proposition as evidently absurd, is the same faculty which recognizes another proposition as evidently true. It is, indeed, because of its contradicting something evidently true, or something which has been already proved to be true, that the absurd result is seen to be absurd. It is in this way that, in the exact sciences, erroneous data are being perpetually detected, and the sources of error are being perpetually eliminated. But reason seems to have no similar power of detecting errors in the data which are supplied to it from other departments of thought. In the developments, for example, of social habits, and of the moral sentiments on which these principally depend, no results, however extravagant or revolting, are at all certain of being rejected because of their absurdity. No practice however cruel, no custom however destructive, is sure on account of its cruelty or of of its destructiveness to be at once detected and rejected as self-evidently wrong. Reason works upon the data supplied to it by superstition, or by selfish passions and desires, apparently without any power of questioning the validity of those data, or, at all events, without any power of immediately recognizing even their most extreme results as evidently false. In Religion, at least, it would almost seem as if there were no axiomatic truths which are universally, constantly, and instinctively present to the mind—none at least, which are incapable of being obscured—and which, therefore, inevitably compel it to revolt against every course or every belief inconsistent with them. It is through this agency of erroneous belief that the very highest of our faculties, the sense of obligation, may and does become itself the most powerful of all agents in the development of evil. It consecrates what is worst in our own nature, or whatever of bad has come to be shown in the multitudinous elements which that nature contains. The consequence is, that the gift of Reason is the very gift by means of which error in belief, and vice in character, are carried from one stage of development to another, until at last they may, and they often do, result in conditions of life and conduct removed by an immeasurable distance from those which are in accordance with the order and with the analogies of Nature.

These are the conditions of life, very much lower, as we have seen, than those which prevail among the brutes, which it is now the fashion to assume to be the nearest type of the conditions from which the human race began its course. They are, in reality and on the contrary, conditions which could not possibly have been reached except after a very long journey. They are the goal at which men have arrived after running for many generations in a wrong direction. They are the result of Evolution—they are the product of Development. But it is the evolution of germs whose growth is noxious. It is the development of passions and desires, some of which are peculiar to himself, but all of which are in him freed from the guiding limitations which in every other department of Nature prevail among the motive forces of the world, and by means of which alone they work to order.

It is in the absence of these limitations that what is called the Free Will of Man consists. It is not a freedom which is absolute and unconditional. It is not a freedom which is without limitations of its own. It is not a freedom which confers on Man the power of acting except on some one or other of the motives which it is in his nature to entertain. But that nature is so infinitely complex, so many-sided, is open to so many influences, and is capable of so many movements, that practically their combinations are almost infinite. His freedom is a freedom to choose among these motives, and to choose what he knows to be the worse instead of the better part. This is the freedom without which there could be no action attaining to the rank of virtue, and this also is the freedom in the wrong exercise of which all vice consists. There is no theoretical necessity that along with this freedom there should be a propensity to use it wrongly. It is perfectly conceivable that such freedom should exist, and that all the desires and dispositions of men should be to use it rightly. Not only is this conceivable, but it is a wonder that it should be otherwise. That a Being with powers of mind and capacities of enjoyment rising high above those which belong to any other creatures, should, alone of all these creatures, have an innate tendency to use his powers, not only to his own detriment, but even to his own self-torture and destruction, is such an exception to all rule, such a departure from all order, and such a violation of all the reasonableness of Nature, that we cannot think too much of the mystery it involves. It is possible that some light may be thrown upon this mystery by following the facts connected with it into one of the principal fields of their display—namely, the History of Religion. But this must form the subject of another chapter.

ASTRONOMY.

DISCOVERY OF A NEW COMET.

Mr. Lewis Swift, of Rochester, N. Y., has announced to the Smithsonian Institution the discovery by himself, on Sunday morning, May 1st, 1881, of a bright comet in Right Ascension $0^h\ 0^m$, Declination 37° North. The comet rises a little before the sun and is moving slowly south.

Professor A. Hall makes the following enquiry in "The Analyst:" "Observations on the motions of the sun-spots have also established the fact that the sun is not strictly a fixed body, around which the earth revolves, but that it has a motion of its own thro' space."—*Physiography*, by T. H. Huxley, F. R. S., 2nd Ed., p. 365. How can the above fact be determined by observations of the sun-spots?

NOTES.

A BILL has been introduced into Parliament for the purpose of authorising the erection of a system of pneumatic clocks in the streets of London.

AUSTRALIAN TELEGRAPHY.—At the close of 1879 some 31,556 miles of telegraph wire were at work on the Australian Continent, and 40,634 miles with Tasmania and New Zealand added.

IT is said that the Telephone Company in Belgium has inaugurated a system by which subscribers leaving word the previous evening may be awakened at any hour in the morning by means of a powerful alarm.

COLONEL PARIS, the head of the Paris fire brigade, has concluded his report on the destruction of the Printemps Establishment by proposing that large warehouses be compelled to light by electricity.—*Nature*.

A FEAT IN NICKEL-PLATING.—The plating company of the Berlopton Lane Works, Stockton-on-Tees, have successfully plated with nickel three large cylinder covers for marine engines, on account of Messrs. Maudslay, Son, and Field, the eminent engineers. The largest cover weighs nearly 1¾ tons, and is 6 ft. 6 in. in diameter. It was plated in the large nickel bath, and polished all over successfully by one of Fenwick's patent portable polishing machines. The same company have also just nickel-plated the whole of the bright parts of Sir James Ramsden's yacht engines, built by the well-known firm, the Barrow Shipbuilding Company (Limited), also, some locomotive domes and safety-valve covers.

BOOKS RECEIVED.

ANIMAL LIFE AS AFFECTED BY THE NATURAL CONDITIONS OF EXISTENCE, by KARL SEMPER, Professor of the University of Würzburg. With two maps and one hundred and six wood cuts. D. Appleton & Co., New York, 1881.

Naturalists have been more than once taunted with too much philosophizing over the Darwinian theory, that they were content to form fanciful ideas as to how this or that difficulty could be hypothetically explained, and that fundamental causes—equally fanciful—were imagined to account for results which were actually observed.

We apprehend that if the Darwinian theory is to become a scientific dogma, the future course of naturalists must lie in the direction of applying the test of exact investigation to the hypotheses already laid down. The task is doubtless a laborious one, and Professor Semper himself says that to prove by experiment the truth of many of these hypotheses long and deep researches are indispensable, or the student will find himself wrecked upon insurmountable difficulties.

There are a number of eminent naturalists whose works tend in this direction, and Professor Semper now leads the van of those who would systematically apply themselves to this task.

Considering that Variability is one of the properties of the animal kingdom which might be most easily traced by exact investigation to its efficient causes, Professor Semper has made it the subject matter of his book, and to facilitate the task of himself and others, has presented a general view of those facts and hypotheses which bear upon the subject, and which are either of universal significance or appear to offer favorable subjects for experimental treatment.

It is not claimed that this work is a complete review of even this branch of the enquiry, but it lays out a plan fortified by a long array of facts, showing how the enquiry may be systematically conducted. It is thus a protest against casual and disconnected observation, and as such may be read with profit by every student.

The introductory chapters are of much interest, dealing with some of the salient points of the Darwinian theory. The plan of the work is also explained and the reader introduced to the subject.

The main body of the book is divided into two sections. The first treats of the influence of *inanimate* surroundings, and in this division Professor Semper directs attention to the influence of food, light, and temperature upon organisms. The results attributable to water, both still, and in motion, are explained, and finally other influences are considered.

In the concluding portion of this work, the influence of *living* surroundings is discussed in such a masterly manner, as to be of the highest service to those studying this subject.

We notice that the subject of the geographical distribution of animals is discussed by Professor Semper, who points out the chief difficulties in bringing into accord the various hypotheses, suggested to explain the undoubted fact that certain species overstep the limits apparently assigned to them by Nature.

Whenever any extensive resemblance between the faunas of two distinct countries is discovered or imagined, a hypothetical history of upheavals and subsidences is suggested, to form a bridge of mainland, as a mode of accounting for this resemblance. This appears to be a favorite theory of Mr. Wallace, and Professor Semper himself admits that such must have been the case in some instances, as he himself found an Indian elephant on Mindanao, the most southerly of the Philippines, for such an animal could scarcely have made the passage by sea. Nevertheless, Professor Semper considers these hypothetical connections of the islands and mainland as not sufficient by themselves to explain even those facts which are already known, as to the distribution of Indian and Australian forms on the islands lying between the two continents.

He further states that "until the question is finally settled whether two parallel series of animal development might not have proceeded independently in two countries remote from each other, we can never venture to regard the resemblance of two faunas as conclusive evidence of their primæval actual connection; nay, it even seems to me that the two historical series of species of the horse, recently discovered both in Europe and America, may, on the contrary, be regarded almost as a proof that each series was developed independently on the two continents, and yet led to the same result: namely, the production of the horse."

Leaving this, however, as an open question, Professor Semper advances a theory for accounting generally for irregularities in the geographical distribution of animals, by suggesting that the action of currents and winds cooperated in a large degree in producing the results which are found to exist.

As a means of distributing animal life it is evident that winds and currents conveyed certain animals from place to place, but Professor Semper points out that these influences frequently acted as a hindrance to the distribution of species. Every navigator is familiar with the fact that currents have a dividing power, shown by the tendency of objects to drift to the edge of the stream, although they may have fallen into the middle of it. This tendency of the current to clear itself—or clean itself—is stronger in proportion to its rapidity and strength. Hence, objects torn by a stream flowing between two islands from the one lying to the left of it, could be borne to that on the right side only under specially favoring circumstances; and *vice versa*, those brought from the right could never, or very rarely, be carried to the opposite side. Thus a mixture of the faunas of the two islands might be hindered, simply by the action of the current flowing between them, except in the case of free swimming animals having the power to overcome the mechanical resistance of the current. In considering the striking circumstance that the islands lying close to Africa have quite a different fauna from that of the neighboring continent, this influence is mentioned as a factor.

Between these theories, offered respectively by Mr. Wallace and Professor Semper, no positive conclusions can be drawn, for want of sufficient evidence based on general conclusions, and while neither can be rejected as erroneous, both must remain open for future discussion. Professor Semper, however, claims one advantage that his hypothesis appeals for proof only to such elements as can be brought under direct observation, while that of Mr. Wallace is intrinsically incapable of demonstration by observation.

The work concludes with sixty pages of closely-printed notes, containing much useful information, and a long array of facts bearing on the subject matter of the work.

We have probably shown by this review that Professor Semper has presented a work of the highest value to every naturalist, and we can assure the general reader that he will find in it material that will engross his attention, and cause him to regret the moment when he arrives at the last pages.

ERRATUM.

Mr. Dopp desires to make the following correction in his paper in the last issue:

"In my article on page 200 of "SCIENCE," the expression $\lambda = \frac{v}{n}$ and $\lambda' = \frac{v}{n'}$ should have been $\lambda = \frac{V}{n}$ and $\lambda' = \frac{V}{n'}$ V being the velocity of light.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

PUBLISHED AT

TRIBUNE BUILDING, NEW YORK.

P. O. Box 3838.

SATURDAY, MAY 14, 1881.

THE alleged discovery of a new motive force for driving engines, patented by Professor Gamgee, of Washington, is already condemned on theoretical grounds, both in this country and in Europe.

The principle involved is not a new one, and, so far, all previous attempts in the same direction have ended in failure. In this case, Chief Engineer Isherwood, of the United States Navy, gives an endorsement to Professor Gamgee's scheme, which has caused some eminent physicists to give an attention to it which perhaps it hardly deserved.

From what we can gather, we understand that Professor Gamgee proposes to work his engine with ammonia, taking advantage of the fact that in a liquified state it boils at—37.3° Fahr., and that at 60° Fahr. it exerts a pressure of seven atmospheres—or, say, 100 lbs. to the square inch.

Authorities differ on this subject, but so far as liquid ammonia is concerned, it is stated as follows: "That at atmospheric pressure, and a temperature of 62° Fahr., 1 lb. of the gas occupies about 23 cubic feet, while 1 lb. of liquid ammonia would occupy only 36 cubic inches."

According to Mr. Isherwood, the "zero-motor" is an apparatus in which liquid ammonia can be vaporized under considerable pressure by means of the heat in water, or in the external atmosphere, and the gas so obtained is used to propel a piston through a cylinder—the gas being employed with the greatest measure of expansion found possible.

At this point the difficulty is presented of returning the ammonia to the boiler. Professor Gamgee offers no explanation, but claims to be able to accomplish it by some method he has invented. He asserts that in its expansion the liberated gas is refrigerated and diminished in bulk, and becomes partially liquified at the end of the stroke of the piston, when it is exhausted and returned from whence it came.

Against this, Professor Simon Newcomb and some English writers assert, that in the absence of demonstration to the contrary, it will absorb as much power to convert the ammonia gas into the liquid form as the latter will give out when vaporized.

In the "zero-motor" Professor Gamgee professes to have an engine capable of exerting great power, and without the necessity of using any fuel, and indirectly the claim is made of solving successfully the problem of perpetual motion.

Apart from some fundamental errors which underlie the scheme, many theoretical difficulties could be suggested, but as a practical test of "the discovery" will probably be made, further discussion may profitably be postponed until the result of the trial is known.

It will no doubt be a genuine surprise to all students of nature to learn that a German scientist has found fossil plants and animal forms in most of the meteorites (chondrites) which he has examined for the purpose.

DR. OTTO HAHN, who has taken a prominent part in the discussion on the "*Eozoön canadense*" has, in the usual way, prepared sections of many of these bodies. These he has had photographed and thereby attained a result which is independent of the microscopist's vision. Dr. Hahn claims that they show many forms of plants and animals in a fossil state contained in their mass, of which the highest forms are crinoids, corals and allied species. He has placed this collection of sections in the hands of Dr. Weinland of Tübingen, (formerly of Philadelphia) for thorough classification.

We regret that we are unable to endorse this interesting discovery. Professor Whitfield, superintendent of the fossils and minerals in the American Museum of Natural History, has seen Dr. Hahn's drawings and was unable to verify the presence of the organic forms referred to. He attributed Dr. Hahn's error to a too sanguine temperament, and an "imagination which bodies forth the form of things unknown."

WE are indebted to our Washington correspondent for a brief mention of an interesting paper by Dr. George M. Sternberg, on "A Fatal Form of Septicæmia in the Rabbit, produced by Subcutaneous Injection of Human Saliva."

Dr. Sternberg recently published a translation of Dr. Antoine Magnin's work on Bacteria, and has had considerable experience in making investigations on septic organisms. He now asserts that the human saliva carries with it a deadly poison, which will kill a rabbit in forty-eight hours; other animals also appear to be influenced more or less by the same cause, while still others—the dog, for instance—resist the

poison. Some salivas are more fatal than others—that of Dr. Sternberg being especially virulent. It will be noticed in our report that Dr. Sternberg attributes the poisonous element to the presence of Micrococci—having found this form of Bacteria both in the saliva employed and in the poisoned blood of the victims.

These facts may be considered in conjunction with experiments by M. Pasteur in the same direction.

SCIENTIFIC SOCIETIES IN WASHINGTON.

THE BIOLOGICAL SOCIETY.—At the last two meetings the Society has listened to four papers: A Fatal Form of *Septicæmia* in the Rabbit produced by Subcutaneous Injection of Human Saliva, by Dr. George M. Sternberg; On the Mortality of Marine Animals in the Gulf of Mexico, by Mr. Ernest Ingersoll; A Statistical View of the Flora of the District of Columbia, by Professor Lester F. Ward; and Notes on Scale Insects, by Professor J. H. Comstock. All of these papers were of the highest scientific value, prepared by specialists in connection with their own immediate investigations. Dr. Sternberg has been making experiments for the past two years under the patronage of the National Board of Health, concerning the causes and development of epidemic diseases. In the course of his labors he has made careful observations with reference to inoculation, and in the paper referred to above gave the Society the benefit of his experiments on saliva injected under the skin of the rabbit. As an elaborate report will appear in the proceedings of the Board of Health, it will be necessary to state only the conclusions arrived at, which are as follows: The rabbits impregnated died invariably in less than 48 hours. Other animals which did not succumb were afflicted with sores. Dogs resist the poison, guinea pigs yield less readily than rabbits, fowls escape entirely. Some salivas are more fatal than others; that of Dr. Sternberg is especially virulent. The presence of Micrococci in the saliva, in the blood of the poisoned animals, and in that of animals infected with this poisoned blood led the author to the conviction that the evil effect was owing to these minute bacteria.

Mr. Ernest Ingersoll, who has been studying the waters of the Gulf of Mexico in the interest of the U. S. Fish Commission, reported that in certain years there occurred a great mortality among the marine animals. In the years 1844, 1854 and 1878 such disasters had been noticed, but the one most injurious in its consequences was in the year 1880. Oysters, clams, fish, and even sponges, were involved in the universal ruin. The beaches were so thickly covered with the dead bodies that the inhabitants were driven from their homes. Various attempts were made to account for the phenomenon, but with indifferent success.

Professor Ward is preparing a work to be entitled "A Catalogue of the Flora of the District of Columbia." It will include all the phænogamous plants and the vascular cryptogams. The number of species enumerated is 1233, distributed among 526 genera, as follows:

Polypetalous	genera,	173	Species,	354
Gamopetalous	"	169	"	388
Monochlamydeous	"	47	"	122
Monocotyledonous	"	120	"	321
Coniferæ	"	4	"	7
Vascular Cryptogams	"	13	"	41
		526		1233

Professor Ward then proceeded to give the census of these species with reference to the orders, to the position of the district north and south, and east and west, as well as in comparison with local floras which have been described with sufficient accuracy.

Professor Comstock's paper on the *Coccidæ*, or scale insects, was a very entertaining treatment of a very dry subject. The group under discussion is usually regarded as the most uninteresting of all the animal kingdom as well as the most anomalous. It is true that the lac of commerce and that of Arizona is the product of these insects, but the most of them are worthless or pernicious. They infest greenhouse plants and most of our useful fruit and timber trees. A specimen was exhibited which had been taken from Europe to Los Angeles, Cal, and back to Washington, upon a lemon, and at the end of its nine-thousand-mile trip was as lively as ever. The method of hatching, of the deposit of the meal, or lac, and of moulting in the male and female, were described and illustrated with drawings and cabinet specimens. The method of classifying these animals into species has been a very uncertain one. Even the later used characteristic, namely, the series of pores or openings on the penultimate ring not being always invariable. Professor Comstock has found the fringe on the last segment of the abdomen to be the most constant specific characteristic. An interesting point in the paper was a discovery made by Mrs. Comstock, that the poisers behind the wings are furnished with a hooklike process which fits into a groove on the back of the wing and helps to sustain it in flight.

THE ANTHROPOLOGICAL SOCIETY.—The entire session of the Society at its last meeting was occupied with the reading and discussion of a paper read by the Rev. Clay McAuley upon the Seminole Indians still remaining in Florida. Of this once formidable but now humbled tribe there remain in the vicinity of Lake Okeechobee 208 individuals, 37 families, 22 camps, and 5 settlements. There are no half-breeds among them, the occurrence of such a birth would probably subject the author to torture or death. They are healthy, have an abundance of food, and are probably increasing. The men are tall, well proportioned, erect, lithe, and graceful. The women are shapely, agreeable, vigorous, and many of them handsome. Dr. McAuley singled out three, whom he characterized as the stately, the beautiful, and the handsome among all the Indians whom he had visited. A very minute description was given of the dress, ornament, customs, and language of these people. A full report will appear in the publication of Major J. W. Powell's Bureau of Ethnology.

THE ULTRA-GASEOUS OR RADIANT STATE OF MATTER.*

BY PROF. H. S. CARHART.

The announcement by Mr. William Crookes, F. R. S., some six years ago, that he had produced mechanical motion by the direct impact of waves of light created a profound impression in the scientific world. But when it was found that the Radiometer, which was supposed to exhibit this new action of light, carried a system of blackened vanes, delicately balanced in a very high vacuum, it impressed most physicists as being an interesting form of heat engine receiving its supply of heat by absorption of radiant energy.

Mr. Crookes subsequently adopted the same view, which was the only tenable one, and investigated the subject in a long series of exceedingly skilful and ingenious experiments. His researches on the Radiometer formed the introduction to a more extended series of investigations into the movement of the residual gas of very high vacua, under the influence of heat and the negative discharge of electricity. These investigations carry us to the very farthest boundary of matter thus far attained, and furnish an ocular demonstration of some of those molecular movements that have heretofore been merely imagined. In fact the phenomena observed are such that Mr. Crookes has felt himself justified in announcing a fourth, or ultra-gaseous state of matter. Such an an-

*Lecture delivered before the New York Electrical Society on May 5, 1881.

nouncement startles us by its boldness, and encounters the opposition of our conservatism. I shall have the pleasure of reproducing a part of Mr. Crooke's experiments before you with tubes made after his models, and recently imported; and at the close of the exhibition I hope you will be able to draw your own conclusions.

Let us first prepare the way from our study of the subject by a clear presentation to our minds of the exact differences between the solid, the liquid, and the gaseous states. We shall then be able the better to judge whether this new claimant is sufficiently differentiated from ordinary gases to warrant its being set aside by itself.

I. A solid is composed of distinct molecules separated from one another by spaces which are large compared with the diameter of molecules themselves. These molecules, which are the indivisible units so far as all *physical* changes are concerned, are held rigidly in a fixed relation to one another by cohesion, a force which acts only across these invisible inter-molecular spaces, and the intensity of which depends upon the chemical constitution of the body. The force of cohesion is counterbalanced by the motion of the individual molecules, the energy of this motion constituting the heat of the body. As the temperature rises, the amplitude of vibration increases, and the force of cohesion is diminished by an increase of distance between the molecules. When the temperature falls the reverse process takes place.

Molecules of matter, in the solid state, retain fixity of position about their centres of oscillation; and any attempt to change the relation of these centres, by distorting the body, calls into action resistances opposing the change of form.

II. When the temperature rises so high that the molecules lose their fixity of position, and are released from the rigid thraldom of cohesion, so that they can apparently roll round one another without changing the distances of their centres, then the solid becomes liquid. As the force of cohesion differs with each kind of matter, so the temperatures of liquefaction also differ. In liquids the cohesion is much diminished but not entirely overcome by the energy of molecular oscillations, which we call heat. A liquid is characterized by taking the form of the containing vessel, by its surface becoming horizontal, and by its equal transmission of applied pressure in all directions. The state of liquidity is due to intermolecular motions of much greater amplitude than those peculiar to the solid state.

III. The temperature still rising, the molecules are finally released entirely from the force of cohesion, and move about in every conceivable direction with enormous and constantly varying velocities. The mean distance between them is sufficiently great to render cohesion inoperative; but they come into constant collisions with one another, now colliding, and now rebounding, changing their direction of motion and perhaps their velocity with every impact. On account of this rapid molecular motion and the absence of cohesion in gases, they tend to expand indefinitely; and they transmit pressure by multitudinous collisions among the molecules, and exert pressure on the walls of the containing vessel by innumerable impacts against its interior. Place a small, closed balloon, partly filled with air, under the receiver of an airpump and exhaust. The balloon distends more and more as the exhaustion proceeds, because of this molecular bombardment against its inner surface, the external coun eracting pressure being withdrawn. In much the same way an impenetrable sheet of metal might be kept suspended horizontally in the air by bullets fired vertically against its under surface. The dynamical principles concerned in the two cases are identical. When a gas is heated, the velocity of the individual molecules increases, and they exert greater pressure on the walls of the containing vessel by their impact, or by expansion secure a longer free path for themselves between successive collisions with one another. This mean free path, or mean length of path, is known to be about $\frac{1}{250000}$ of an inch at the average or normal pressure of the air, while the mean distance between the molecules is about one seven-millionth of an inch, according to the late Prof. Clerk Maxwell. Accordingly a cubic inch of air at normal density must contain the cube of 7,000,000 or 343 quintillions of molecules. Each of these molecules, moreover has, perhaps, millions of encounters every second, the number varying with the kind of gas considered. The state of gaseity is therefore pre-eminently characterized by innumerable molecular collisions, from which proceed all the properties constituting the ordinary gaseous state of matter; and this state continues so long as the motions of the molecules are in every possible direction, and the collisions almost infinite in number. Under such conditions the mean length of path of the molecules, or the distance traversed between two successive collisions, is extremely small compared with the dimensions of the containing vessel, only $\frac{1}{250000}$ of an inch.

Such are the distinctions existing between the solid, the liquid, and the gaseous states, distinctions depending entirely upon molecular aggregation. In the snow or frost crystal, for instance, the molecules of water are grouped together in a definite structural relation; the application of heat destroys the structure, the molecules becoming more nearly individualized by a certain increase of independence or freedom of motion, and the solid becomes a liquid; a still further rise of temperature increases this molecular independence to such an extent that their only physical relationship depends upon innumerable collisions with one another. If now, by any means, molecular independence can be rendered so nearly complete that the hits may be disregarded in comparison with the misses, then the free path of the molecule between the hits may become comparable with the dimensions of the containing vessel, the properties which constitute gaseity are reduced to a minimum, and matter is exalted to an ultra-gaseous state. The residual gas is then in that peculiar state when it has ceased to have the power of adjusting its own pressure; and consequently the phenomenon of diverting the molecules by suitable means into any paths at desire will be possible. Such is the ultimate result of gaseous expansion. As the rarefaction proceeds the number of molecules in a given space becomes smaller and smaller, and the mean length of path greater and greater, the molecular collisions diminishing as the free path increases.

At an exhaustion of a millionth of an atmosphere the number of molecules in any given space is reduced to one millionth of the number at the ordinary pressure; each molecule has a million times more room to move about in, and its mean length of path becomes about four inches (1,000,000 times $\frac{1}{250000}$ in.) If now the rarefaction be carried to another millionth, the space appropriated to each molecule is then increased a million million times, but the distance between the molecules becomes only one seven-hundredth of an inch, and a cubic inch contain seven then not less than 340 millions of molecules, according to Prof. Clerk Maxwell. This rarefaction is about 50,000 times further than the best mercurial air-pump can attain. A *gas* transmits pressure instantaneously in all directions by innumerable molecular collisions; an *ultra gas*, or "radiant matter," has lost the power of adjusting its pressure because of the infrequency of collisions among the molecules.

If then a bulb about four inches in diameter is exhausted to a millionth of an atmosphere, the residual gas in it will have lost the power of rapid adjustment of pressure to equality at every point. Hence any extraneous force, like heat or electricity, may "infuse order into the apparently disorderly jostling of the molecules in every direction by coercing them into a methodical rectilinear movement. * * * * * And according to the extent to which this onward movement has replaced the irregular motions, which constitute the very essence of the

gaseous condition, to that extent have the molecules assumed the condition of radiant matter."

Let us now see to what extent Mr. Crookes has reached these conditions in his Radiometer and radiant matter tubes.

In the Radiometer the blackened vanes become heated by absorbing radiant energy (both heat and light), and they project the contiguous gaseous molecules from their surfaces by communicating to them their molecular motion, much as a vibrating drum-head would project into air grains of sand strewn on it. An increase of pressure is thus produced between the heated lamp-black and the gaseous residue; but this pressure is not transmitted throughout the whole bulb because of the relative infrequency of collisions among the molecules at this degree of exhaustion. Hence the molecules are projected forward against the cooler bulb in right lines, and the blackened vanes retreat because the repulsion between them and the gaseous residue is mutual. [A Radiometer projected on the screen by an oxyhydrogen lantern; also, a diagram showing the paths of the projected molecules].

Mr. Crookes investigated the Radiometer with an ingenuity and a variety of detail that left nothing to be desired. Moreover, his visualization of the molecular motions taking place in this little instrument prepared him for a further research into the motion of the residual gas in Geissler tubes. The dark space around the negative pole, which broadens as the exhaustion proceeds, and the brilliant stratification displayed by many Geissler tubes, were hints in the line of his special studies. I cannot forbear, at this point, to call your attention to the vibration of the air in a sounding pipe, made visible by very light, precipitated silica powder. The resemblance between the beautiful segmentation of the pipe by the thin, vertical planes of silica powder, and the stratification of a Geissler tube, is most marked and suggestive. [A finely stratified Geissler tube shown; and a glass pipe, containing silica powder, and vibrated by a whistle projected on the screen]. As the silica planes limit the free swing of the air particles in the pipe, so the bright portions of the vacuum tube show when the residual gases of contiguous segments encounter each other—the vibration being set up by the passage of electricity. And it may be observed here that as the transmission of sound is the onward transference of energy by motion, so the passage of electricity is the transference of energy from one point to another by means of another form of motion.

The exhaustion which answers best for a Geissler tube is comparatively low. I have frequently obtained beautiful stratification in a tube six feet long, exhausted by a good air-pump. Mr. Crookes carried the exhaustion much further and obtained entirely new results. The first noticeable feature was the gradual broadening of the dark space surrounding the negative pole as the exhaustion advanced [dark space tube, exhibited a transverse sheet of aluminum in the middle constituting the negative pole]. This dark space is regarded as the free path of the molecules at this degree of exhaustion. It increases as the exhaustion proceeds, and contracts when the exhaustion diminishes. The molecules of air are projected normally from the negative pole, and the illumination at the boundary of the dark space is due to the collision between the gas projected from the negative pole and the more slowly moving molecules advancing toward it. Here, then the lines of molecular pressure, caused by the excitement of the negative pole, are illuminated by the induction spark.

With still higher vacua the free path becomes equal to the dimensions of the containing vessel, and the projected molecules impinge directly against its walls. The molecules stream from the negative pole with enormous velocities and dart across the tube with comparatively few collisions. Their motion is then arrested by the solid matter of the tube. A noteworthy property of this radiant matter then appears. Luminosity is produced by the impact of the projected molecules against solid matter. Phosphorescence, as this luminosity is called, is thus excited, its color depending upon the kind of matter receiving the impact. [Three phosphorescent tubes shown; also a bulb partly filled with phosphorescing material.] English glass phosphoresces a light blue, uranium glass rather dark green, and soft German glass, light apple green. Rubies always shine with a deep red hue whatever the color of the gem itself. The artificial rubies made in Paris show no variation from the real stones in the color of their phosphorescent light. This phosphorescence takes place better at an exhaustion of about a millionth of an atmosphere than at any other. A tube designed to show the dependence of the phosphorescence upon exhaustion, is made by connecting to the main tube a small supplementary tube containing caustic potash, which holds captive a certain amount of aqueous vapor [the tube exhibited]. Turning on the coil, the tube now shows green phosphorescence, but upon heating the potash tube with a small lamp, aqueous vapor is released, the phosphorescence gradually disappears, and is replaced by the stratified discharge of a Geissler tube. Withdrawing the lamp, the vapor is re-absorbed by the caustic potash, the fine stratification widens out slowly and finally retreats towards the potash bulb, while a wave of green light sweeps from the negative pole, driving the last pale stratification into the potash tube. Radiant matter moves in straight lines and absolutely refuses to turn a corner. This peculiarity is shown by a V-shaped tube. [The tube exhibited.] The flood of green light proceeds from the negative pole at the top only as far as the bottom, refusing to turn the angle toward the positive in the other branch. Reversing the current, the illuminated branch follows the negative pole. A striking contrast is thus presented between a Geissler and a Crookes tube; but this contrast is brought out more clearly still by two bulbs exactly alike, except in the degree of their exhaustion. Both are fitted with one negative terminal and three positive ones. With the low vacuum tube the stratification follows the direction of the positive pole, changing its path as that pole is changed. Changing now to the high vacuum or Crookes tube, containing only about a millionth of an atmosphere, and turning on the coil the only light to be seen is the green phosphorescence of the glass. The negative pole is a very shallow cup, and the projected radiant matter crosses its focus and then strikes on the opposite side of the bulb where the impact excites strong phosphorescence. Changing the positive pole produces no change whatever in the path of the projected molecules or the luminosity of the glass. The positive pole exercises no influence whatever upon the direction of discharge of radiant matter from the negative pole. The residual gas is here exalted to the fourth or radiant State, and its free path, under the impulsion of the negative discharge, is entirely across the bulb. Moreover, not only is luminosity induced, but the glass bulb rapidly heats where it receives the cannonade of these invisible balls.

Another peculiarity of radiant matter, depending upon its projection in right lines, is that when intercepted by solid matter it casts a shadow. This large pear-shaped bulb has the negative pole at the small end. A cross cut out of sheet aluminum is placed across the bulb so as to intercept a part of the gaseous molecules streaming from the negative pole. Connecting with the induction coil, the dark shadow of the cross is seen plainly projected on the large end of the bulb. Here the projected molecules pass by the aluminum cross and bombard the walls of the bulb, producing the usual phosphorescence Nothing could show more distinctly than the projection of matter from the negative pole in straight lines.

This bombarding causes the surface of the glass to lose its sensitiveness to intense phosphorescence. The cross is hinged so as to turn down with a slight shake.

Again turning on the coil the rays from the negative pole fall uninterruptedly on the large end of the bulb; the dark cross is now replaced by one more intensely green than the adjacent portions of the glass. The fresh parts of the glass are more susceptible to luminous excitation than the areas previously bombarded. This stenciled image of the black cross, Mr. Crookes tells us, is so persistent that it remained in one case after the glass had been heated hot, so that the end of the bulb was bent in and then blown out again. After re-exhaustion the bright green cross came out plainly in the more intense phosphorescence produced by the electrically projected residual gas. Thus the molecules hammer away upon the glass with sufficient energy to produce a permanent impression.

Since the molecules of the residual gas are driven violently from the negative pole, there should be a recoil of the pole from the molecules. That such is the case is shown by this electrical radiometer. The connections are such that the aluminum vanes constitute the negative pole. The vanes are not blackened but are covered on one side with mica, a non-conductor. The uncovered sides constitute the radiating or projecting surfaces. Turning on the induction current the vanes are repelled and the system rotates rapidly. The phosphorescent spots on the glass, produced by the impact of the molecules projected from the vanes, rotate as the vanes do, giving us a visible image of the process going on in the heat radiometer. In this second form the negative pole consists of a ring of platinum wire. Above this is a fly, composed of mica vanes inclined like the fans of a wind-mill. Turning on the current the matter projected from the wire strikes against the sloping vanes and sets them in motion. But this is not all. I now connect a battery directly with the terminals of the platinum ring, and the passage of the current heats the ring red hot. Directly the fly begins to turn more rapidly than before. Radiant matter is thus projected by heat as well as electricity, and the ordinary heat radiometer is propelled by the recoil of projected radiant matter like the electrical radiometer.

The action of magnetism on this stream of electrified particles is, indeed, curious. When a straight Geissler tube of low vacuum is employed it gives a narrow line of violet light joining the two poles. [This tube placed over the poles of an electro-magnet.] On passing the battery current through the magnet underneath, the violet line is repelled or attracted according to the direction of the currents; but it recovers itself after passing the magnet and proceeds to the other pole. Not so with a tube of high vacuum. This tube contains a mica screen, covered with material which phosphoresces under molecular impact. The radiant matter from the negative pole passes through a narrow opening and impinges upon the screen along its entire length. You observe how the phosphorescence marks the path of the projected molecules. Bringing a strong magnet down over the stream or actuating the electro-magnet, and the luminous path curves toward the side of the tube like the path of a projectile; but in this case the stream does not recover its original direction after deflection, as in the case of the Geissler tube. This same tube is fitted to determine another question of much interest connected with these wonderful phenomena. It is provided with two negative projecting surfaces, and the stream of molecules from each of these may be made to trace its path on the mica screen in a luminous line. Observe the position of this line first from one pole and then the other. What now will be the result if streams issue from both poles at once? If they constitute two currents of electricity in the same direction then we know that they will attract each other; but if they consist of a train of similarly electrified molecules, then they must repel each other Put to the test of experiment we see plainly that the stream lines diverge by mutual repulsion.

We have seen that mechanical action is produced by the recoil from the radiant matter. It is equally true that strong mechanical effects may be produced by the impact of these swiftly moving molecules. This tube is ingeniously constructed with a pair of glass rails running from end to end. Along them rolls freely the axle of a small wheel with broad vanes as paddles. The poles are so situated that the radiating molecules may strike against the vanes. Turning on the induced current, the stream of swiftly moving molecules strikes against the vanes on one side of the wheel and sets it running along the rails. Reversing the current, the wheel stops and returns on its track. [Tube projected on a screen by oxy-hydrogen light.] Another tube has been devised to show both magnetic deflection and mechanical action on the screen. The negative pole is a large, shallow cup. A mica screen intercepts the converging streams of radiant matter.

Behind the screen is placed an easily-revolving mica wheel provided with vanes and making a sort of paddle wheel. So arranged the molecular rays from the pole are cut off from the wheel, and no movement is produced. Placing a magnet over the tube the rays are deflected so as to pass above the screen and the wheel begins to revolve. Reversing the magnetic poles, the deflection is in the other direction, and the wheel now rotates like an undershot water-wheel. Even at this high vacuum of about a millionth of an atmosphere, enough matter remains in the tube to produce a sort of molecular wind under the impulsion of the negative discharge. Radiant matter produces heat as well as mechanical motion when its motion is arrested. The negative pole in this tube is a cup or concave projector. The radiant matter comes to a focus near the cup and then passes on toward the other end of the tube. But on bringing a magnet near it the stream of radiant matter is deflected so as to strike the side of the tube, producing a green, phosphorescent spot. The nearer the magnet approaches the greater the deflection of the stream and the smaller the spot. Covering the side of the tube with wax and placing it in front of the lantern, a dark image of the tube is projected because of the opaque wax. But with the coil in action the approach of the magnet deflects the radiant stream, the tube is heated by the impact of the molecules, the wax melts and becomes transparent, and the light from the lantern passes through.

The heat generated by the arrest of radiant matter is further shown by a bulb of special device. It has a negative pole of aluminum in the form of a concave projector. In its focus is fixed a piece of platinum foil. Turning on the coil, the projected molecules impinging against the platinum at last raise it to a red heat. Indeed Mr. Crookes has actually melted iridio-platinum in such a focus. We are accustomed to see powerful heating effects produced by currents of electricity traversing rather poor conductors; but here red hot platinum glows with the invisible cannonade of innumerable molecules of the air we breathe.

These effects take place indifferently with hydrogen, carbonic acid gas, and air at this high vacuum. The only difference appears to be that the phosphorescence begins at different pressures with the different gases. The results obtained depend, therefore, not on chemical properties, but on the physical, molecular condition of the gaseous residues. These phenomena are so entirely different from those obtained at ordinary degrees of exhaustion, that Mr. Crookes appears to me to be justified in considering that he has at last verified Faraday's early hypothesis of matter in a radiant state. Mr. Crookes has well said that, "In studying this fourth state of matter we seem at length to have within our grasp and obedient to our control the little indivisible particles which, with good warrant, are supposed to constitute the physical basis of the universe. We have seen that in some of its properties radiant matter is as material as this table, while in other properties it almost assumes the character of radiant energy. We have actually touched the

borderland where matter and force seem to merge into one another, the shadowy realm between the known and the unknown, which for me has always had peculiar temptations. I venture to think that the greatest scientific problems of the future will find their solution in this borderland, and even beyond; here, it seems to me, lie ultimate realities, subtle, far-reaching, wonderful."

GREAT ASTRONOMICAL TELESCOPE.

The greatest refracting telescope in the world—Lord Rosse's is a reflecting telescope—has been constructed for the Vienna Observatory by Mr. Howard Grubb, at his celebrated manufactory of astronomical instruments, at Rathmines, near Dublin. We give an illustration, from a sepia drawing of it by Mr. G. Browning, and abridge the following account of it from a description received at this office.

The idea of crowning the observatory at Vienna with a refracting telescope of surpassing power was conceived by the Austro-Hungarian Government about five years ago. Such a building was worthy of the best instrument that could be constructed. Every visitor to the Austrian capital must be struck by it, standing upon a site of between fourteen and fifteen acres at a height of 200 feet above the city, and extending 330 feet in length and 240 feet in width. Desiring to possess the finest telescope which could be procured, the Government commissioned Dr. Edward Weiss, now Director-General of the Observatory at Vienna, to visit all the principal observatories and workshops in the world. He recommended that the task should be confided to Mr. Grubb, of Dublin, who was ordered to construct a refracting telescope of at least 26 inches aperture. A commission was appointed by the Austro-Hungarian Government to superintend the work. It was composed of the following gentlemen: The Earl of Crawford and Balcarres, Dr. Higgins, the Earl of Rosse, Professor Stokes, of Cambridge, Professor Ball, Astronomer Royal for Ireland, Dr. Stoney, Secretary of the Queen's University in Ireland, many years connected with Lord Rosse's observatory, Dr. E. Reynolds, professor of chemistry, Trinity College, Dublin, and Mr. Walsh, Austro-Hungarian Consul in Dublin. On the 16th ult. the Commissioners reported their unanimous approval of the finished instrument.

The general form of the telescope is that known as Grubb's modified Gramme, and is similar to the well-known standard equatorial which he constructed for the Earl of Crawford and Balcarres, Dr. Huggins, Oxford University, Berlin, Cork, and other places. It possesses all the modern improvements and special arrangements of an ingenious character, which are rendered desirable by its great size. The length of the tube is 33 feet 6 inches, and the aperture is 27 inches. The tube is entirely of steel, 3½ feet in diameter in the centre, and tapering to each end. The entire moving parts, including the tube, polar, and declination axis, counterpoise and various adjustments weigh between six and seven tons; yet the whole apparatus is under such control that one person can move it about and manipulate it with the utmost ease. The mechanism is remarkable for its solidity and strength, as well as for its exquisite delicacy.

In order to render the motion of such ponderous instruments sufficiently easy, the makers are generally obliged to reduce the diameter of the axes, particularly that known as the declination axis, to an extent that makes one almost alarmed for their safety, to say nothing of their stability. Mr. Grubb, however, has mastered the difficulties of the position by a peculiar and most interesting system of equipoise, by which he is enabled to make his axes so large and solid as to ensure stability and give perfect confidence without sacrificing the ease of motion. The application of antifriction apparatus to the polar axis has been already successfully effected, and was a simple problem, but Mr. Grubb has the exclusive merit of applying it to the declination axis, which is a task of great and complicated difficulty, demanding the highest scientific skill.

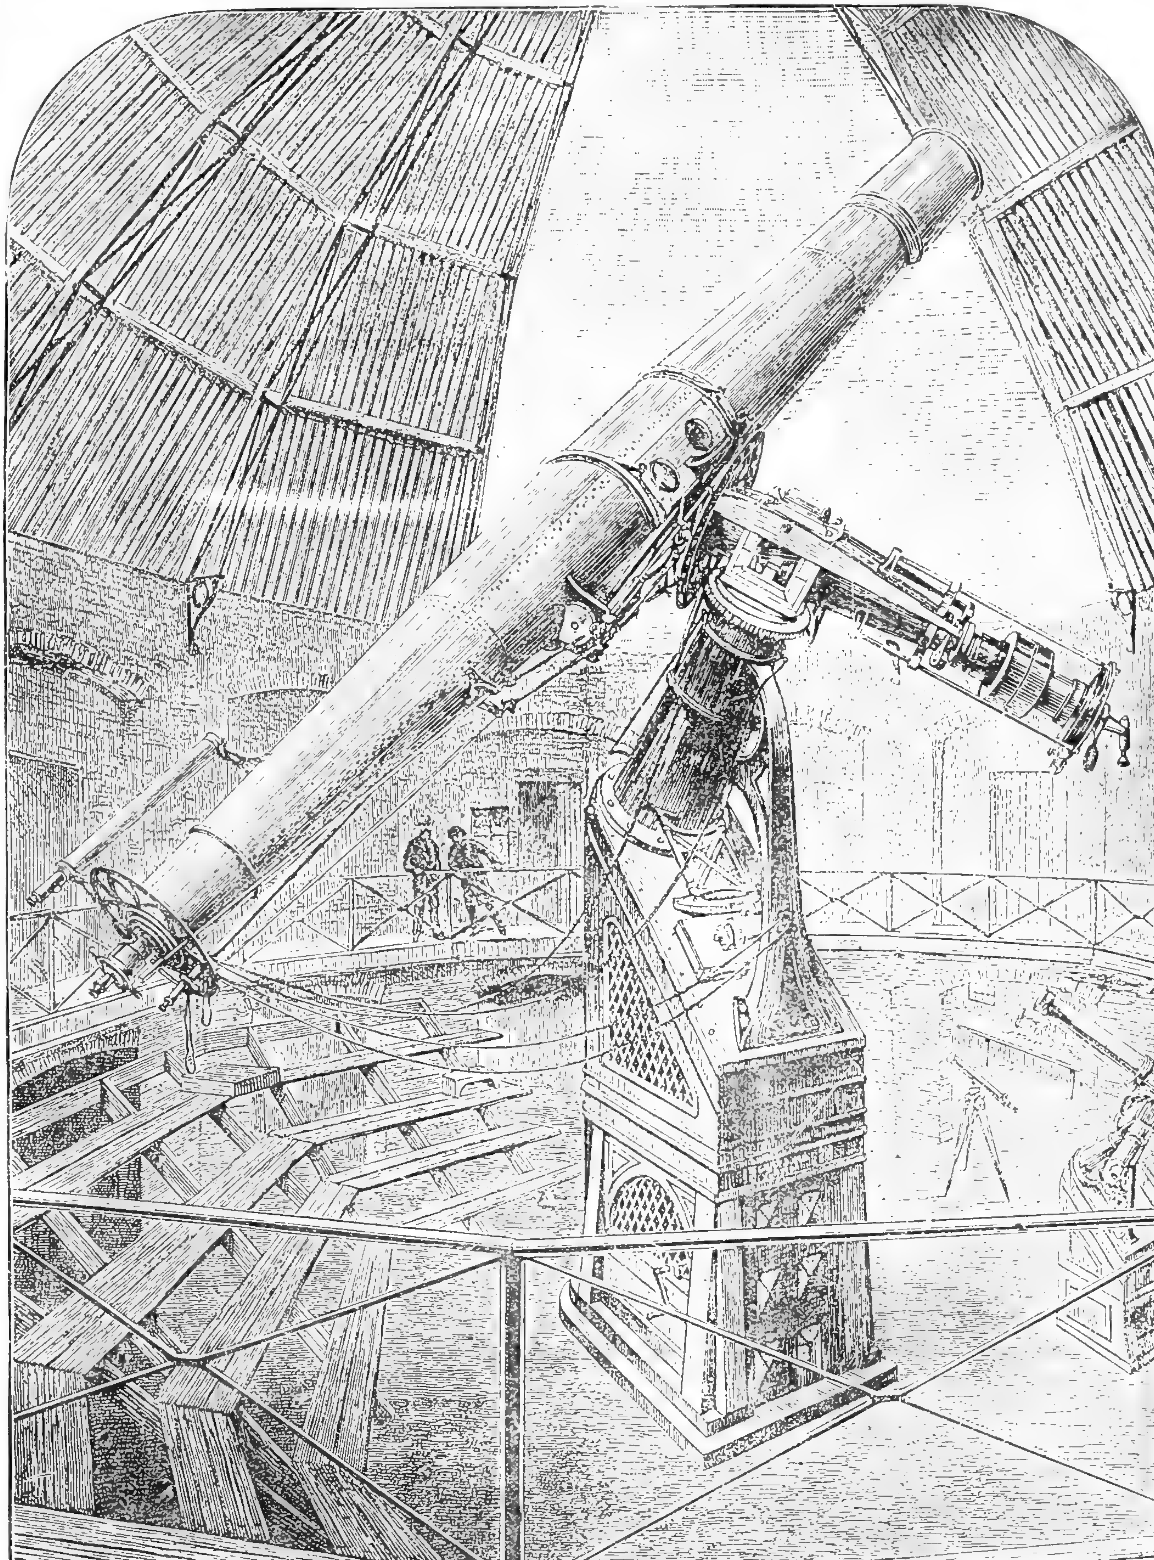
Another remarkable feature in the work is the ingenious arrangement by which the circle can be read with the utmost ease and certainty. It is usually a very troublesome operation with large telescopes to read the circle, and when the circles are about 20 feet or more from the ground the labor and delay which it involves are very formidable. In Mr. Grubb's instrument, the circles are carefully and accurately divided on a band of gold, and by a system of reflectors, at once beautifully simple and ingenious, the observer can without stirring from his chair read all the circles of the instruments through one little reader telescope attached to the side of the main telescope tube.

The setting of the telescope is massive and graceful. The frame on which it rests down to the ground level is of cast iron, and there are chambers of considerable size at the base. In the lower one, which is entered by a door at the end, is a clock for driving the instrument in order to follow the paths of the heavenly bodies. The castings of which the frame is formed are of about ten tons weight, and are of simple but not inelegant design. The clockwork is controlled by Mr. Grubb's novel frictional governor, and is also furnished with his new electric control apparatus. There are two right ascension circles, each 2 feet in diameter, one read from the eye end of the telescope and the other from the ground floor. The declination circle is 5 feet in diameter, and is read from the eye end of the telescope. All the circles are divided on an alloy of half pure gold and half pure silver, which is found to be very white and not liable to corrode or tarnish.

The material for the object glasses was procured from M. Feil, of Paris. The protracted delay in procuring this material for the work was a subject of great anxiety to Mr. Grubb, and occasioned heavy additional outlay on his part. In October, 1879, however, discs were obtained, which in working gave good promise, and in December last he was able to report the work finished—his part of it being, in fact, accomplished in less than half the time stipulated by the agreement with the Austro-Hungarian Government. His task was practically trebled by the difficulty experienced in obtaining pure discs. The success of his undertaking is regarded with great satisfaction and with national pride. He has supplied equipments to most of the modern observatories, but this telescope is his greatest achievement.

THE *Athenæum* prints an interesting extract from a letter from Prof. Draper, giving a description of the progress he has made in photographing the nebula in Orion:—"I have succeeded," he says, "in taking stars in it of the 14.1, 14.2, and 14.7 magnitudes of Pogson's scale. Prof. Pickering has made a series of measures on these magnitudes especially for me at the Harvard College Observatory. You will perceive that we have photographed stars which approach the *minimum visible* of my 11 in. telescope, and we may, therefore hope shortly to photograph stars actually too faint to be seen with the eye in the same instrument. The nebula, which was exposed 104 minutes, extends over an area of about 15′ in diameter, though, as it becomes fainter toward the exterior parts, it is difficult to determine its precise limits." This is a great advance; no star of less than the ninth and a half magnitude has hitherto been photographed.

A CURIOUS magnetic property of the meteoric iron of Santa Cattarina (Brazil), has been lately observed by Professor Lawrence Smith. Small detached fragments, not weighing more than 0.1 to 0.2 gr., were very weakly affected by a magnet; but on being flattened on a piece of steel, with a steel hammer, they become very sensitive to it. By heating red-hot, the particles were made to be still more easily attracted than by flattening. The meteoric iron in question contains 66 iron, 34 nickel.



THE NEW TELESCOPE, VIENNA OBSERVATORY.

THE POLARIZATION OF SOUND.

AN EXAMINATION INTO THE NATURE OF VIBRATIONS IN EXTENDED MEDIA.*

By S. W. Robinson,

Professor of Physics and Mechanics, Ohio State University.

The phenomena of polarization of light have heretofore presupposed transversal vibrations of particles of the luminiferous ether. Such vibrations have not only been supposed transversal when polarized, but primarily, or when in their primitive condition. It is proposed now to show that no necessity exists for considering the vibrations in light as transversal in front of a polarizer; and furthermore to show that in all probability luminous vibrations are primarily longitudinal.

It is well known that light can be radiated, reflected, refracted, diffracted, diffused, can be made to interfere and can be polarized. All these effects are known to be common to sound, except the last, and it is for the sole purpose of explaining this in light that the convenient theory of transversal vibration has been set up by physicists, for the single case of luminous vibration. It is to be noticed that transversal vibrations are not to be assumed impossible when sufficient cause exists. It is simply assumed that the cause is insufficient when a material particle is made to vibrate from the action of a disturbance at a remote single centre transmitted to the particle considered; the centre, the transmission, and the particle considered, being supposed as belonging to a homogeneous medium of indefinite extent. As regards the nature of the vibratory movements of particles of luminiferous ether may we not justly ask that, if we can go through such a range of density as from platinum to hydrogen without a change in the nature of the vibrations where, as we rise in the scale of etheral tenuity, shall longitudinal end and transversal begin? Why should the luminiferous ether, now considered as a substance, have a peculiar form of vibration? If ether undulations can be polarized, why not undulations generally? These questions are not answered by the highest authorities. The short of it all seems to be that if polarized light had never been discovered probably the device of transversal vibrations never would have been set up. Indeed, the eminent author M. J. Jamin, says in his three volume work on Physics at the outset, in his lesson on polarization, and subsequent to the treatment of interference, diffraction and other phenomena: "What has been said previously of the movement of luminous waves is absolutely independent of the directions of the vibration." This is good authority for limiting the *transversal* theory to polarization, authority with which doubtless all physicists will agree on this point. It is, therefore, only necessary to polarize sound to place all the known effects of luminous waves in common with sound waves, or to make the theory of longitudinal vibrations universal.

Assent to the above notions will be the more readily given after noticing the consideration that, in polarized light it is not necessary to suppose the vibrations transversal till after passing the polarizer, and that the latter probably imparts an effect equivalent to a lateral impulse, as due to its one-sided action upon the ray transmitted, thus giving cause for vibration which are more or less transversal; the same being true for undulations in air, water, iron, platinum, hydrogen, luminiferous ether, etc., without exception.

But independent of all questions of polarization we find powerful evidence of the unity of system, for vibrations in all possible media; evidence which, in one case at least, is employed as the basis of a rigorous mathematical demonstration of the impossibility of existence of perpetual motion. This latter named evidence is the famous principle of Helmholtz regarding the action of natural forces among mutually interacting material points, viz.: that the forces must be central forces and functions of the distance, and hence motions of remote particles can only be longitudinal with reference to the centre of force. This principle, considered aside from luminiferous ether, will be universally accepted as truth. But what is the criterion for making an exception of any homogenous substantial medium; even luminiferous ether? Indeed, if any criterion exists for such an exception, it consists simply in a desired convenient means for explaining polarization: a theory of transverse vibrations, which, though convenient and probable beyond the polarizer, has thoughtlessly and without need, been extended to the front of the polarizer, and to undulations in the primitive conditions, where, as shown above, no necessity exists for transversal vibrations. That the necessity for transversal vibrations in primitive rays of light is entirely wanting, let it be granted for the sake of an argument that the source of light, such as the sun or a gas burner, is capable of exciting vibrations in the adjacent medium, which are in all possible directions immediately at the radiant. At a considerable distance from the radiant, the effect upon a single particle will be the resultant of action of all the particles immediately surrounding the radiant, and transmitted by and through the intervening medium; such a resultant impulse can hardly be admitted to be otherwise than longitudinal. Or again, a particle near the radiant imparts an impulse to the adjacent particle. If the passive particle is in direct line with the active one, the impulse received will be in direct line also, and the direction of motion of the two particles coincides. The similar direct action of a second particle upon a third will also be in the same line, and so on indefinitely. At a distance of several hundred or thousand times the diameter of the radiant the line of vibration indicated will be almost perfectly longitudinal irrespective of where the first particle considered is situated about the radiant. That is to say, a particle at the surface of a radiant vibrating in a line of direction tangential to it or transversal, may be considered as transmitting its vibration from particle to particle in a direct line, and hence to the best advantage; and still, at a distance this direct line becomes nearly a line of longitudinal vibration for a remote particle.

Thus all lines of direction of vibration will pass through the radiant or be tangent to it, so that in sunlight tne rays, and the directions of vibration, will all lie within the visual angle of the sun, or within about half a degree of arc, and hence almost perfectly longitudinal.

These considerations all confirm the principle of Helmholtz. And that remarkable principle, together with all considerations presented above, and all which can possibly result from a careful study of the subject of transmitted impulses, go to confirm a universal law of longitudinal vibrations for primitive rays in all possible substantial media, and to antagonize the notion of transversal vibration.

Hence, if light can be polarized, why not undulations generally. The writer, after much study of the subject, became convinced of the possibility of this about eight years ago, and six years ago apparatus was made for putting the matter to an experimental test. Want of time prevented, and further study determined a modification of the apparatus which was made over two years ago. This apparatus was successful in verifying all my preconceived notions in the matter, but owing to extended study and matured views of the principles involved, the experiments simply confirmed, without developing new theories or unanticipated facts. I propose now to describe the apparatus and give the results.

The means adopted for polarizing the undulations is the same as that for polarizing light by reflection. It is well known that when sound passes from one medium into another whose velocity of sound differs, the sound is

refracted. Recent investigations of Henry, Tyndall and others have indicated that when sound encounters a change of density of medium, as when passing from clear atmosphere into a wall of fog, there is a reflection of sound. Altogether there seems no doubt but sound acts like light in these respects, that is, on meeting a change of refractive power, it is both reflected and refracted, as light is at the surface of water or of glass. The reflected light is found to be always more or less polarized, perfectly so for the so-called polarizing angle. This polarizing angle of incidence is such that, as discovered by Brewster for light, the reflected and refracted components of a single ray, as they strike away from the point of incidence are at right angles. As reflected light is polarized, reflected sound was supposed to be also.

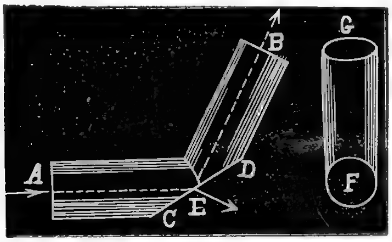


FIG. 1.

Applying the laws of Fresnel and Brewster—1st, that the index of refraction is equal to the ratio of the velocities of the waves in the media; and 2d, that complete polarization is obtained for the particular case of right angled reflected and refracted component rays, we are guided to the proper conditions. We conclude that any two substances having different velocities of propagation of waves may be selected For instance, two gases, like hydrogen and air, any two liquids, any two solids, a solid and a gas, or, generally, any two media whatever. Considerations of convenience would indicate air and illuminating gas, and these were chosen for the present purpose. The velocities of propagation in air and coal gas being as 1125 and 1420, the index of refraction, according to the first law above, is $n = 1{\cdot}26$. The second law gives for the polarizing angle of incidence, tangent $i = n = 1{\cdot}26$, or $i = 51\frac{3}{4}^{\circ}$, the rays or waves being in the gas. To realize this incidence upon a surface of separation between the gas and air, the cool gas was placed in L-shaped tubes, *AB*, Fig. 1, having a portion cut away at the angle, as shown at *CD*. The branches of the L make equal angles of $51\frac{3}{4}^{\circ}$ with the normal to *CD*. A delicate membrane was gummed to the tube covering the opening at *CD*, also shown at *F*, the object of which was to retain the gas and maintain a polarizing surface, *CD*. The arrow at *A* indicates a ray which is incident at *E*, and is then in part refracted outward at *E* in a direction perpendicular to the reflected component *EB*. Each tube was about one inch in diameter and three inches long. A number of these were made of tin, each with one end slightly larger than the other, so that they could be joined up, stove-pipe fashion, to any desired extent. Being cylindrical, the plane of one L-piece could be placed at any angle with the plane of the preceding one, according to the desired polarizing test.

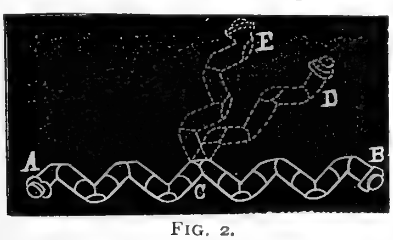

FIG. 2.

Fig. 2 shows the manner of joining the tubes, giving the effect of nine polarizing surfaces, like nine plates of glass in light arranged at the polarizing angle. The nine plates of glass can be used in two parts—one part, 4 for instance, serving as a polarizer and the remaining 5 as analyzer. The ends at *A* and *B* were capped with membranes and the whole filled with illuminating gas. Thus *AC* may serve as a polarizer and *CB*, or *CE*, or *CD* as analyzer. When arranged as in *ACB* or *ACE* all conspire to the same effect of polarization; but when arranged as in *ACD*, the plane of all the L-pieces in *CD* being at right angles to that of those in *AC*, the effect of one part antagonizes that due to the other, and to a maximum degree as regards the angle. Partial effects may be obtained with intermediate angles between 0° and 90°. Again, we observe that the L-pieces of Fig. 2 may be alternately crossed, so that no two contiguous ones will be parallel. It is believed that this arrangement will give the greatest possible antagonistic effect; also while all Ls are in one plane it is not necessary that they be arranged in a zig-zag line, like *AC* and *CE*, but may be indiscriminately connected in that plane. The few experiments made with the above-named arrangements gave very marked results. Of course it need not be confined to nine or any particular number of the L-pieces.

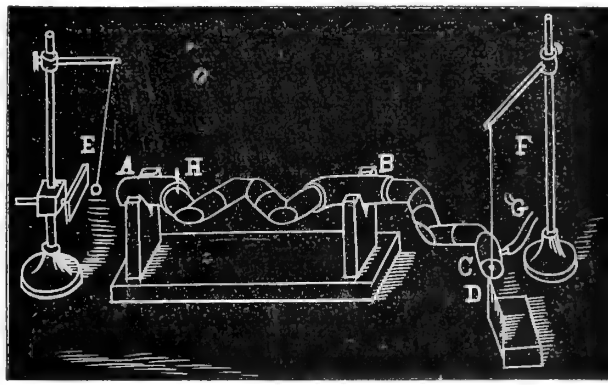

FIG. 3.

It was found, however, wanting in convenience. The apparatus finally adopted is that shown in Fig. 3. A different number of L-pieces were used at different times. The portion *AB* is the polarizer and *BC* the analyzer. The joint at B was kept tight with beeswax; the ends at *A* and *C* were capped square with the same membrane material as were the angles of the Ls, giving, when charged with illuminating gas, a continuous zig-zag column from *A* to *C*. The L-pieces of the polarizer enter half Ls at *A* and *B*, the latter having a common axis and resting in bearings at *A* and *B* in the standards, as shown. The object of this is to enable the experimenter to turn the polarizer readily from cross to parallel, etc. This convenient arrangement of the polarizer is due to my assistant, Mr. Wright. Although applied to the polarizer, it is evidently equally applicable to the analyzer instead. The half L angles were not covered with membranes, but left solid, with gradual inside curvature. Membranes might have been applied here with partial polarizing effect. The half L solid angles are supposed to have detracted in a measure from the percentages of polarization obtained; but this sacrifice is more than compensated for by the greater convenience and constancy of conditions obtained. If this arrangement gives decisive results, of course, more perfect apparatus would. The illuminating gas was admitted by a nipple and rubber hose at *C*, the same flowing the length of tubes and issuing in a small jet at *H*; my assistant kept this ignited, and used the flame length as a pressure indicator, and it served admirably.

The first trials were made by blowing an organ pipe in front of the membrane *A*, to agitate the gas column.

A small mirror was attached to the membrane *C*, reflecting a pencil of light upon a screen. The deportment of the image indicated complex and inadmissible vibratory movements of gas column, and besides quantitative indication was found preferable to qualitative; thereupon the quantitative impulse and indicator pendulums were adopted, as shown at *E* and *F* respectively, Fig. 3. An ivory ball, ¼ inch in diameter, suspended by a thread of 8 inches length, was used at *E*, and so placed that when at rest the ball would just touch the membrane at *A*. The impulse was imparted by bringing the ball back against the stop, shown by means of a spatula held in the hand, and then allowing it to swing free against the membrane, each time with a definite, predetermined arc. So much of the impulse as reaches *C* knocks the pendulum *F* through a certain arc, the same being measured on the scale *D*. This pendulum was a small, hollow glass bead, suspended by a silk fibre and trained delicately against the membrane. The bob carried a pointer for the scale *D*.

In the experiments the ball would be dropped against *A* some five or ten times, at intervals of about ten seconds, the corresponding deflections at *D* being noted and recorded; then the polarizer would be turned 90° and like observations noted. Again, 90° would be turned off, etc., etc.; occasionally the length of impulse arc would be changed, or more or less L-pieces applied, and in each case a large number of observations made.

In the experiments the initial pulse seemed to be followed by a series of vibrations in rapidly decreasing amplitudes; but it is believed that the initial pulse is equivalent to a genuine sound wave, or an undulation. Evidence of soundness of this view is found in the fact that the velocity of sound can be satisfactorily determined by similar pulses sent through tubes of 25 or 50 feet length. It was evident that the initial pulse only, was concerned in the first swing of pointer at *D*.

Observations were made with as few as one L in the polarizer, and two in the analyzer. But the results were small, averaging about 4 per cent. But during the noting of 455 individual results of observation the number of Ls in the polarizer ranged from 1 to 3 and in the analyzer 2 to 3. The average of all of these 455 observations gave a percentage of 8.87 hundredths of quenching of the polarized beam. That is to say, where the analyzer, in light, entirely quenches the polarized beam in turning through 90°, in the above 455 experiments only 8.87 hundreths of the polarized ray was quenched.

But as a higher percentage was looked for, the instrument itself was now examined for possible faults. The membranes were all found under considerable tension. whereas, of course, they should be perfectly free from it. After completely slackening, then, as was supposed, the experiments were continued with the following results:

POLARIZATION CONTINUED.

Coal Gas in L-tubes and Air outside.

Individual results.

Polarizer having 4 Ls and Analyzer 5 Ls.

	=	+	=	+	=	+	=	+	=
	6.0	6.0	8.0	5.0	6.5	5.8	6.2	6.0	6.0
	6.0	6.0	7.5	5.5	6.5	5.5	6.0	5.2	6.2
	6.2	6.0	7.0	5.3	6.3	5.6	6.5	5.2	7.2

			7.0	4.0	6.3	5.3	6.3	5.8	6.8
							6.3	5.2	6.4
Means	6.07	5 83	7.19	5.01	6.43	5.50	6.30	5.37	6.34

In this series each value given in any column is the number of divisions on the scale *D*, Fig. 3, of the deflection of the indicator pendulum bob. After obtaining one column of results the polarizer, *AB*, was turned 90°, and the next column obtained. Thus the several columns were obtained. The = and + signify that the polarizer and analyzer are in parallel or perpendicular planes respectively.

On completing this series of observations air was passed into the L tubes, completely displacing the coal gas, so that the membranes were now suspended in mid air. Other conditions remained the same. The indicator pendulum now responded to the same impulses so slightly as to be barely observable, but not measurable, and they were apparently the same for the polarizer in all positions; that is to say, when air was upon both sides of the reflecting surfaces there was almost no appreciable reflection. This evidently should be the case, as the light membrane itself is now the chief cause of reflection. This, compared with the results obtained with gas in the tubes, shows that a considerable reflection is due to surfaces of separation of gases differing in density.

As regards the polarization, we observe that every mean under "=" is larger than any mean under "+," a fact which cannot be assumed accidental, nor explained on any other ground than polarization. To find the percentage of this in a single result, we have

Means of the above series.

	=	+
	6.07	5.83
	7.19	5.01
	6.43	5.50
	6.30	5.37
	6.34	
Means,	6.47	5.43

$$\text{Per cent.} = \frac{6.47 - 5.43}{6.47} = 16.1.$$

Whole number of observations, 80.

At this point the membranes were again examined and found to have appreciable tension, though supposed to have been entirely slackened at the beginning of the series of observations just cited. It seemed that the dampness in the gum used, expanded the membranes so that they became tight after thoroughly drying as the experiments went on. It was thereupon determined to slacken them with the utmost possible care, and continue the observations The following table of individual results was then obtained in the manner explained above, the membranes being constantly watched for entire slackness.

POLARIZATION CONTINUED.

Coal Gas in tubes and Air outside of tubes.

Polarizer having 4 Ls and Analyzer 5 Ls.

Individual results.

	=	+	=	+	=	+	=	+	=	+	=	+	=	+

	1.5	1.1	2.0	1.0	1.3	1.0	1.9	1.0	1.7	1.1	1.5	1.1	2.0	1.0
		1.0	2.0	0.9	1.2	1.0	1.8	1.0	1.7	1.2	1.5	1.0	2.0	.0.9
			2.1	0.9	1.3	1.0	1.6	1.0	1.8	1.0			2.1	0.9
					1.5	1.0		1.1	1.7	1.0				
								1.1	1.7					
								1.1	1.6					
Means	1.44	1.00	2.00	1.01	1.45	1.00	1.71	1.07	1.67	1.19	1.50	1.00	2.00	1.01

Polarizer turned 90° immediately following each column of results.

For gas displaced by air, other conditions the same; deflection, 0.00.

The smallness of these results, compared with those of the previous series, may be explained on the ground of extreme and entire slackness of the membranes; also the slackness is still further evinced by the fact that, when air displaced the gas no deflection of the indicator pendulum was observable in response to the impulses. Tense membranes would have turned the sound waves somewhat, and in the manner of the rebound of a drumstick from its drumhead.

To obtain the percentage of polarization effect, we have:

Mean of the above series.

=	+
1.44	1.00
2.00	1.01
1.45	1.00
1.71	1.07
1.67	1.19
1.50	1.00
2.00	1.01
Means, 1.68	1.04

$$\text{Per cent. } \frac{1.68 - 1.04}{1.68} = 38.1.$$

Thus with the apparatus working most perfectly, the analyzer succeeded in extinguishing or quenching 38 per cent. of the polarized wave, a percentage too great to be mistaken. Considering the analyzer and polarizer as equally efficient, the real percentage of polarization by polarizer would be 62 per cent., and of the analyzer 62 per cent., as is evident from the fact that 62 per cent. of 62 per cent, is 38 per cent. Thus, either part of the apparatus obliterates over half of the wave attempting transmission, a fraction which would be unmistakably visible in polarized light.

These results establish the following facts for sound waves or for undulations, viz.:

1st. A decided reflection occurs at a surface separating two gases of different density, confirming the views of Henry and Tyndall in this regard.

2d. In repeated reflection from such surfaces the intensity of the final component varies with the relative positions of those surfaces, the same following the laws of polarization in light, from which we conclude that longitudinal undulations can be polarized.

With sound polarized, we complete the list of effects for longitudinal undulations which are known to light, viz.: radiation, shadows, reflection, refraction, diffusion, diffraction, interference and polarization; for the laws are common for like conditions, viz.: for intensity of radiation in ambient space, $\frac{I}{d^2}$; in parallel space, $\frac{I}{d^1}$; in prismatic space, like a tube, $\frac{I}{d^0}$; for shadows, reflection, refraction and interference as well known; for diffusion, as when a steam whistle is sounded, filling the air with its resounding ring; for diffraction, as sound waves diverging rapidly after passing a narrow space between buildings, like light in passing a narrow slit and diverging; and, finally, for polarization, as above. In studying these comparisons we should recollect the vast difference between the properties of undulations in heavy, and ethereal media. Thus the wave length is very great and the velocity of propagation very small in sound as compared with light. This seems sufficient to account for the greater definition of shadows in light; but when a slit or an obstacle is made as narrow for light as for sound, in comparison to wave length, the diffraction divergence is probably about alike; that is, the divergence at a linear slit in light, or between two buildings in sound; or again the shadow of a silk fibre in light and a sound shadow of Bunker Hill monument, for instance, are about alike considering wave length. With these considerations it may be reasonable to expect incomplete or only partial polarization with such apparatus as employed above.

The conclusions to which we are conducted by the foregoing may be summed up as follows:

1st. That vibrations in extended media, produced from the action of a remote single centre of disturbance, can only be longitudinal, even in light.

2d. That vibrations will be to some extent transversal when due to two or more centres of disturbance not in the same line, as when two or more independent co-existent systems of undulations combine into one, or when a simple system is modified by such lateral disturbance as a reflection or a refraction.

3d. That undulations, to be in a condition called polarized, probably consist of vibrations which are transversal, and that no necessity exists for assuming vibrations transversal in front of a polarizer.

NOTE.—As regards longitudinal, oblique, transversal, etc., in the foregoing, the estimate is to be taken by comparing the direction of the line of vibration of a particle with that of propagation of the wave.

My acknowledgements are due to Mr. Clarence H. Wright, who, while a student in my physical laboratory last Spring, rendered valuable aid in the experimental work.

ASTRONOMY.

COMET (*a*) 1881—SWIFT.

The question of the best method of transmitting telegraphic announcements of astronomical discoveries has just been discussed by the leading European societies, and a system has been devised by which this information may be comprised in a message of sixteen words. Thinking that perhaps a better way existed of doing the same work, the Boston Scientific Society has adapted a telegraphic code to the needs of the occasion, and this system has just received a practical test. The announcements lie within the province of the Smithsonian Institution, and it was accordingly decided to transmit by cable the elements and ephemeris. These here given were computed at Dun Echt Observatory, in Scotland, by Drs. Copeland and Lohse, and have been distributed in this country to astronomers by special circulars of the Boston Scientific Society. That set which was computed at Boston, for the Society, by Mr. S. C. Chandler, Jr., has already been cabled to Europe, and distributed by mail, from the Observatory of Lord Crawford, to astronomers in England and the Continent.

The cablegram received at Boston consisted of sixteen words, and the translation is here appended. According to the same code, the announcement of discovery could be comprised in a message of seven words, which would itself contain check words against possible error in transmission.

The elements and ephemeris computed at Dun Echt, on Monday, May 9, were transmitted by cable to Boston in the following message: "Decimosexto erective contextual bewitchery anticly demonstrative courageously sputter arithmancy stomachical auriferous suety bayou synecdochically bissextile eminently." The translation of this message is as follows, viz:

ELEMENTS OF SWIFT'S COMET, 1881 (*a*).

Per. Passage, 1881, May 20.67, Greenwich Mean Time.

May 10,	0	38	32	+26	46	1.69
14,		56	48	21	35	
18,	1	17	32	15	54	
22,		40	48	9	55	2.32

Computed by Dr. R. Copeland and J. G. Lohse, from observations made at Dun Echt Observatory. The light at discovery is taken as unity.

By means of control-words in the message, it is absolutely known that the elements are those computed yesterday in Scotland, and it is proposed to cable in the same way the first elements and ephemerides of future comets, obtainable at either terminus, until the code has been most thoroughly tested. J. RITCHIE, JR.

ON A METHOD OF ISOLATING THE MAMMALIAN HEART.

By H. Newell Martin (Johns Hopkins University.)

To obtain a mammalian heart isolated from the rest of the body and keep it alive for a time sufficient to allow the examination of the effect of various conditions upon its activity has long been a physiological desideratum. The frog's heart has for years been the subject of minute study but hitherto the mammalian heart has been a baffling object. It seems to have been forgotten that while the frog's heart is a spongy structure having no arteries of its own, the mammalian heart is a dense organ dependent for its life on a continuous blood flow in its capillaries; and all attempts hitherto made, so far as I know, have been efforts to apply to the mammal the methods found successful with the frog, with merely the addition of arrangements adapted to keep up the comparatively high temperature at which the mammalian heart normally beats. By working in another way I have recently succeeded in keeping the mammalian heart alive for more than an hour, and beating with perfect rhythm and normal force; the organ is thus made almost as available for study as the heart of the frog. The method adopted is as follows: The animal having been narcotised and the chest opened, the aorta is tied just beyond its arch; then the trunk which, in the cat, gives origin to the right subclavian and the two common carotids, is ligatured close to its origin, and a cannula put in the left subclavian; finally, the inferior and superior venæ cavæ and the azygos vein, and the root of one lung are tied.

Artificial respiration is of course started so soon as the thorax is opened, and kept up henceforth. The course of the circulation is thus:—left auricle, left ventricle, commencement of aorta (and along the left subclavian to the cannula which is connected with a manometer), coronary system, right auricle, right ventricle, pulmonary vessels of one lung, and then back to the left auricle; in other words, the only section of the systemic circulation left is that through the vessels of the heart itself. Since the physiological actions taking place in the lung are among the best known of all occurring in the body, they may be eliminated, and we have practically an isolated and well-working living mammalian heart for study. The nerves going to the heart may be divided if desired, but that is hardly necessary as the want of blood-flow in the nerve centres of the body incapacitates them after a very short time, and they no longer are capable of exerting any influence on the heart. It is possible, however, that changes in the lung vessels may affect the results of experiments made on the heart's work under different conditions (*e.g.* when defibrinated blood is sent into it from a vein under various pressures, or when drugs are administered to it), and an investigation of the nerves, if any, governing the lung vessels must be undertaken as a preliminary to a further study of the direct action of various conditions on the heart's work.

EDINBURGH ROYAL SOCIETY.

There was a very large attendance at the meeting of the Edinburgh Royal Society held recently, to hear Professor Helmholtz, who was announced to make a communication "On Electrolytic Convection." Professor Helmholtz stated to the Society the results of certain later experiments which he had made in working out his theory of electrolytic convection—experiments which, he said, had succeeded better than his former ones had done. He had entered upon his experiments on account of certain objections that had been made to Farraday's electrolytic law, in connection with experiments which showed that a very feeble galvanic current could be kept up by moderate electro-motive force between platinum plates dipped in a slightly acidulated solution, even if the electro-motive force of the battery was not sufficient to decompose the water. He had found, in his earlier experiments, that the only effect of the current was to absorb oxygen given off from the atmosphere and to form a new portion of water, and that the whole electrolytic effect was, not to decompose water and to produce a new quantity of elements—hydrogen and oxygen—but only that on the surface of one plate of platinum oxygen was collected and taken away from the surface of the other. He had, therefore, called these currents electrolytic convection. It was not really a decomposition, but only a transport of one of the products of electrolytic decomposition from one place to another. In his later experiments he had got rid of the atmospheric oxygen, by inclosing the whole electrolytic fluid in a sealed glass vessel. As a result, he had found that the smallest electromotive force, down to the thousandth of a Daniell's cell, produced a strong deflection which went immediately back to zero, that there was no continuous current, and that, if they broke the current, they got a deflection of the same character in the opposite direction to the first and direct one. Sir William Thomson, in speaking on the paper, stated that Professor Hemholtz's theory of electrolytic convection formed quite an era in electrolytic chemistry. Sir William himself made a communication "On the average pressure due to impulse of vortex-rings on a solid," following up inquiries suggested by Helmholtz's vortex theory. Professor Tait stated the result of certain calculations which he had made "On the crushing of glass by pressure," and which had been suggested by his recent inquiry as to error-corrections in the use of the *Challenger* thermometers. The result was that with cylindrical tubes made from ordinary Leith plate-glass, he found the glass gave way under a shear of about 1-250th, and that the strength of the tube was greater as the walls were thicker and the internal diameter decreased. But, however thick the walls might be, or however small the internal diameter, a pressure of 22 or 23 tons on the square inch would inevitably crush the strongest glass.

NOTES.

M. Daudigny, electrical engineer in Paris, has sent to the Municipal Council a petition asking for authority to establish on the top of the Colonne de Juillet a large electric lamp fed by a magneto-electric machine of fifty horse-power. This enormous light is to be diffused by a large reflector of special construction.—*Nature.*

Signor Manet, we learn from an Italian journal, whitens the albumen of blood by means of the electric light; which is projected by a system of mirrors and lenses, giving a strongly luminous effect. The time required varies according as the albumen is more or less separated from the fibrine. In general, 24 hours suffices to give complete decoloration.

Professor Loomis appears still to be experimenting in aerial telegraphy—telegraphing without wires—and it is now said that he proposes to establish communication, through the current which he claims is always found at a great altitude, between one of the highest peaks of the Alps, in Switzerland, and a similarly situated station on the Rocky Mountains, on this continent.

It has been found by M. Laurent that any ordinary good silvered glass mirror, plane, concave, or convex, and of any thickness, may be rendered a magical one by means of heat. A simple way of doing this is to heat a brass tube, and apply the end of it to the silvered face. If the mirror surface is opposite a screen, the section of the tube is reproduced in white; if the former is turned away from the screen, the image (which is seen only after removing the tube) is dark. A cold tube may be used with a hot mirror, and the experiment may be otherwise varied.

M. Duchemin, the inventor of the compass with a circular magnet, now adopted in the French navy, has recently devised, for correcting compasses, a system of magnetic compensators. In place of the straight magnetic bars generally employed he uses magnets of an annular form. If we magnetise a steel ring, it may have two poles at opposite extremities of a given diameter and two neutral lines. Such rings—round, oval, or of any other form, and with or without interruption of continuity—may be utilised for the correction of a compass, by being placed either on the bridge of the vessel or in the binnacle.—*Revue Industrielle.*

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

TRIBUNE BUILDING, NEW YORK.

P. O. BOX 3838.

SATURDAY MAY 21, 1881.

THE Spring Reception of the American Museum of Natural History, Central Park, New York, and the publication of the Twelfth Annual Report, remind us of the existence of this Institution, and recall its many claims for support from those interested in science, and in the intellectual progress of the people.

The additions and improvements made during the past year make only a short list on the programme, but reflect the excellent management and zeal of the officers in charge of the collections. A large portion of the collections of birds and mammals has been remounted on newly designed stands, the results obtained being most creditable to those who have carried out this improvement.

One of the new features of usefulness recently established is an Economic Department, which will contain specimens illustrating the Economic Botany of all the woods of our country, that are to be used for architectural or building purposes, or in the manufactures, each species being fully represented by specimens of the leaf, flower and fruit.

We fully appreciate the exertions made by the Trustees of this Institution to extend the usefulness of the Museum and to make it a means of teaching the laboring classes the value of scientific knowledge, and its practical bearing on many of the industrial pursuits of life. If such is, at least, one of the objects of establishing this Museum, it is difficult to understand the action of the Trustees in closing its doors on Sundays, that being the only day on which the artisan and mechanic can make a visit, without entailing a direct loss on himself and family. A petition, signed by 16,000 citizens of New York, was recently offered as a direct appeal to the Trustees to accord this privilege to the working classes, and we trust that the board of management, which has always shown a most liberal and enlightened spirit of enterprise in the conduct of this Institution, may reconsider its late decision on this subject.

The city of New York has provided a costly building for the Museum and recently appropriated $35,000 to improve the approaches. In the Report of the Trustees now before us, a direct appeal is made to the people for financial aid and support. We, therefore, believe the Trustees would confer a direct benefit on the Institution by opening its doors to the people on Sundays; the Museum would doubtless become one of the most popular Institutions in the city, and the Legislature would probably respond with no grudging hand, to provide means for the completion of the building and for its maintenance on a liberal scale.

THE announcement is made of an improved method of storing electricity, by M. Camille Faure, of Paris, the London *Times* asserting that "a box of electric energy nearly equivalent to a million feet, contained within less than a cubic foot of space, intact and potential, has been transported from France to Great Britan."

Sir William Thomson is said to have given some endorsement to the discovery, and tests and measurements are in progress at the laboratory of the Glasgow University.

The principle involved in M. Faure's discovery is understood in this country, and the possibility of its general correctness is conceded. The language employed in the announcement is rather equivocal, and the misuse of scientific terms render the exact extent of M. Faure's discovery a matter of some doubt.

We gladly welcome any progress in electical science; but as the necessity for storing electrical energy is of value only in very rare cases, the practical usefulness of M. Faure's discovery must be limited in extent.

MR. EDISON has courteously responded to a request on our part, to offer his opinion on M. Faure's discovery, and we take pleasure in placing before the readers of "SCIENCE" his reply, received since our own notes were in type.

To the Editor of "Science."

DEAR SIR: The Faure battery is an improvement on the Planté battery.

Planté was, I think, the original inventor of the battery which bears his name, invented some years ago for the purpose of storing up electricity.

Faure has simply made a Planté battery, by some means reducing its resistance, and thus reducing the percentage of loss. This is all there is in it.

Some two years ago I patented and applied a method for using the Planté battery in connection with electric lighting. Yours truly,

THOS. A. EDISON.

SENSIBILITY AND ITS DIVERSE FORMS.

By M. Oltramare.

[Translated From the French, by the Marchioness Clara Lanza.]

From the feeble cry by which the infant affirms simultaneously its birth and its sensibility, to the last long drawn sigh which bids adieu to existence, human life oscillates constantly between two opposite conditions created by the nervous system—pleasure and pain, joy and sorrow.

Being creatures developed to a great extent under the influence of the senses, we experience to an extreme degree, the action of all exterior agents, and atone for such pleasures as are granted to us by our exquisite sensibility, with moral and physical suffering. Not satisfied with momentary impressions, we foresee the influences which are to reach us, and by means of our refined intelligence we create those two great incentives to our actions—apprehension and desire.

Being mortal and also conscious of the fact, we naturally have a presentiment of the final destruction of our bodies, and most of us fear this and look upon it with dread. Nothing of this kind, however, is to be met with in animals. The last hour of life, brutal and violent though it may be and totally unexpected, does not affect them. The dog licks his master's hand affectionately whether it be extended to caress or to kill. He is no more conscious of the possibility of death, than is the ox which is led to the slaughter house.

These higher animals have nevertheless, a sensiblity and individuality upon which their reason depends. They possess what we call instinct. But, as we descend further in the animal world, we see that this function gradually diminishes in proportion as the organisms become simplified, until finally we reach a point, where to cut a living creature in two, not only produces no perception of pain, but actually becomes a means of reproduction, each half being capable of forming a distinct organism precisely like the original.

Lower still, we come to plants, which are living organisms, although Linnæus, a naturalist of the highest rank, refused to admit their sensibility. He says: "Plants live and grow; animals live, grow and feel."

This theory recalls that of Aristotle, when the Grecian philosopher affirmed that all organized beings had a soul more or less developed.

To the vegetable soul he attributed two faculties—growth and reproduction. To the animal soul he assigned four faculties—growth, reproduction, sensibility and motion. To the human soul, five faculties. The four above mentioned, to which was added intelligence, or mind.

Neither Linnæus nor Aristotle admit of any sensibility in vegetable life, and yet this is as great an error as to deny the existence of this same faculty in animals. An error, which is almost universal even in the thinking world, and which certainly should no longer be allowed to exist. From the most minute plant, to the most perfect animal, we find sensibility under various forms, but always corresponding to Claude Bernard's definition: "Sensibility is the *ensemble* of all kinds of modifications, determined in living things by different stimuli, or rather, the aptitude to reply to the provocation of these stimuli by means of modifications."

Bichat distinguishes three forms of sensibility:

1. Conscious sensibility, which presides over relations to exterior movements.

2. Unconscious sensibility, representing internal movements.

3. Insensible, or imperceptible sensibility, so called because it is manifested in other ways than by movement.

Putting aside these fine distinctions, let us admit two forms of sensibility—conscious and unconscious—and we shall be able to demonstrate the possibility of a passage from one state to the other, which proves that they are but modifications of a single attribute.

When we learn to read, it is with considerable difficulty, and we doubt if any one ever mastered the art unconsciously. But later, can we not peruse page after page mechanically, without having an idea of their contents? A transformation has therefore taken place in two kinds of sensibility. It is precisely the same with walking and many other acts in which the brain—that is to say, the conscious agent—plays but a secondary part.

If I prick the foot of a frog with a needle the animal draws it away, and, forewarned by the pain, endeavors to escape. Sensibility here evidently assumes a conscious form. If, however, I decapitate the frog, that is, if I destroy the organ which is the *ego*, so to speak, and once more perform my experiment, the mutilated body draws the leg away, but makes no attempt to escape. The act is purely reflex, unconscious, and in this case, by a simple experimental artifice, I am able at once to substitute the second form of sensibility for the first.

We breathe without knowing it, without the intervention of our will; but if our attention is directed upon this mechanical act, we become immediately conscious of it.

In eating, when once our food is swallowed we know nothing more about it, and yet our sensibility is constantly played upon by these substances, which, physically and chemically modified, are introduced into the circulation of the blood, and thence carried to the anatomical elements, whose sensibility they incite to action. All vital properties, and, consequently, sensibility, reside in those little numberless organic unities which go to form living beings.

There exists a fundamental matter, protoplasm, an amorphous substance endowed with peculiar properties and which Huxley has justly termed the physical basis of life. This protoplasm, which sometimes alone constitutes an inferior living creature, not only moves but attaches to itself minute particles which it meets with in the water, digests them and assimilates them with itself. Ether, the great reagent of sensibility, causes it to lose its transparency, and its movements to disappear. Then, when it is evaporated, the fluid reappears with all the attributes of this inferior life. This is undoubtedly sensibility, but in an unconscious form.

If we begin to mount the organic ladder, we see gradually appear certain cells which specify sensibility, and which, created solely to perform this function, elevate and perfect it. These are the so-called nerve cells. They are scattered throughout living organisms; in the higher animals they are very numerous, and serve to centralize impressions and produce individuality. When they are united to others called cephalic cells, they admit not only of sensation, but also the interpretation of sensation which then becomes conscious.

Thus, beginning with this infinite attribute of living matter which Haller and Glisson, being too timid to call sensibility, termed irritability, we gradually come to the highest forms, whence originate the greater portion of intellectual and physiological phenomena.

In man, all the sensible nerve cells are united in one mass called the cerebro-spinal axis, or the encephalo-medullary mass. It is composed of the spinal cord, the medulla oblongata, and the brain, each of its departments representing one form of sensibility. The spinal cord, properly speaking, corresponds to unconscious sensibility. This is illustrated by that involuntary and spontaneous movement which we call reflex action. The medulla oblongata controls sensations which, like respiration for instance, are frequently unconscious, but which, however, by an effort of the will, can be interpreted as precisely the opposite. The brain possesses the highest form of sensibility, and it is here that the greater part of our physical and intellectual acts are performed. By means of the mi-

croscope we are able to-day, to separate in each nervous centre, the sensitive cells from others of a like kind performing different functions which can be recognized by their shape, dimension and situation.

It is useless here to go into minute details concerning this point. I will call attention, however, to the fact that each sensitive nerve cell is connected with exterior agents by a long fibre called the cylinder axis, which resembles a telegraph wire carefully concealed by a layer of fat, and which, surrounded by numerous protecting membranes, extends throughout portions of the body, and produces sensibility. All these nerve fibres, whose receptive apparatus is in the encephalo-medullary mass, are grouped together and form those little white filments which we designate as nerves. If the end of a nerve is touched, or the root, a modification can instantly be determined, which carried to the nervous centres, becomes a sensation. This sensation is, of course, not always the same, but is in accordance with the determining agent, optic, acoustic, gustative, etc.

If for instance, we cut the nerve which conducts light from the eye to the brain, this sensation will immediately be felt; but if, on the contrary, one of the skin nerves be cut, intense pain will be experienced. It is not, therefore, as M. Delboeuf very justly remarks, the nature of the excitation which determines that of the impression, but the manner in which the brain centre is brought into activity; so that if the optic and acoustic nerves be cut, united and inverted, a noise would be interpreted by a sensation of light, and *vice versa*. The sight of a picture would determine sounds in relation to the brilliancy of the paint employed, while an orchestra would produce colors varying, according to the sounds. Sensations experienced in consequence of exterior impressions do not therefore depend upon the character of the latter, but upon the nature of our nervous cells. We do not feel that which occurs upon our body, but only that which takes place in our brain. If, therefore, all our nerve cells were identical, the exterior world would doubtless produce sensations, but they would be precisely alike, merely differing in intensity. There are certain animals which exist in this condition.

M. Helmholtz and other physiologists have calculated the amount of time required for the transmission of the excitation to the sensitive nerves, and have decided upon thirty metres a second—that is to say, a rapidity equal to an express train advancing at full steam power. Imagine a man whose brain is in Paris while the extremity of one of his limbs is in Geneva, and we will see that it must require precisely four hours and forty-four minutes for a sensation to pass from the latter city to the former.

Given the small distance which separates our extremities from the nerve centres, and the time of transmission is short. It is remarkable, however, that those organs which play the greatest *rôle* in the preservation and conservation of the individual, sight and hearing should be placed in close proximity to the brain. This produces a rapid transmission, and enables a speedy evasion of destructive objects—a disposition evidently acquired by natural selection. It seems, moreover, that the intensity of the impression is in accordance with the distance intervening between the excitation and the nerve centre. We may thus explain the extreme violence of neuralgia of the face and head, as compared with that affecting other portions of the body.

All the various forms of sensibility have an analogous basis. The connection and fundamental identity can be demonstrated by the action of narcotics. We shall see that this is the most general and characteristic property of life, and this axiom can be fully established—that everything which lives, whether animal or vegetable, feels and can be rendered insensible.

It is a well known fact that certain plants rebound when they are touched. The sensitive one closes its leaves while a great number of carnivorous plants shut up like traps as soon as a fly alights upon them, imprisoning and crushing the poor insect which is to serve them as nourishment. The action of day and night has been equally verified in regard to plants. Some flowers only open when the sun shines, while others bloom solely in the dark. It has also been seen that the leaves sometimes turn towards the sun, but these phenomena have been called exceptional, many persons even placing them in the category of problematic occurrences, not wishing evidently to open their eyes to facts which they consider humiliating to the animal species.

Now, however, doubt is no longer possible. Ignorance upon this point can no longer be permitted, and every one must know that animals and plants alike possess sensibility. A great philosopher and physiologist, Claude Bernard, first demonstrated this important truth, not by means of tortuous reasoning, but by the brilliant light of experiment.

Provided with an anæsthetic agent, ether or chloroform, he was able to prove that the highest forms of conscious sensibility and the lowest forms of unconscious sensibility can be successfully affected. When the action of the narcotic begins to take place the *ego* sleeps and with it, conscious sensibility. That is sufficient for the surgeon who can then begin to cut and burn without the shadow of an *arrière pensée*.

Upon continuing the introduction of the fumes of ether into the organism, we see all the forms of unconscious sensibility gradually become annulled subsequent to conscious sensibility. After having acted upon the nerve cell, the anæsthetic destroys the sensibility of all the tissues, that is to say their vital characteristic, causing them to react upon exterior agents—in one word, it kills the individual.

If we pass on from the animal to the plant, we find that ether and chloroform act in identically the same manner. Subject the leaves of a sensitive plant to the fumes of either of these agents, and you will be able to handle them without eliciting the slightest movement on their part. They no longer feel the contact of the hand, for knowing as we do that anæsthetics respect the functions of movement, we can only attribute this inertia to the impotency of the excitation.

Let us now take a rapidly germinating seed, such as that of the water-cress and place it upon a sponge soaked in water. In twenty-four hours it will have blossomed into a tiny stem and root. Repeat the experiment under the same conditions of oxygen, water, light and heat, but place the sponge beneath a glass which has been dipped in ether. The seed will remain intact. It is not dead however, it merely sleeps, for if we remove the glass it will recover from its stupor and by the following day will have sprouted. This unseen life possessed by the seed, life which asks nothing more than to make itself apparent, is, however, subject to external and internal conditions. The first are the necessity of water, oxygen, heat and all physio-chemical conditions; but there is still something else, internal, inherent to the seed itself and constituting the essence of its life. It is sensibility. Destroy this function and notwithstanding the most favorable surroundings, the development will be effectually stopped.

Do not think that this is owing to any peculiarity of the plant and its embryonic condition, for a hen's egg, that latent condition of life of an organism belonging to a comparatively high order, cannot be hatched with any desirable result in an etherized atmosphere.

Germination, the first vital act of the individual, be it plant or animal, is therefore subject to sensibility and in this function we see it appear for the first time. Afterwards it is not difficult to follow it in its course through all the vital acts of the organism. The plant breathes and grows by assimilation, absorbing either the substances contained in the earth, or the carbonic acid in the air. For a long time this gaseous assimilation was

confounded with respiration, and the mistaken conception was spread abroad that plants breathe in direct opposition to animals by absorbing carbonic acid and exhaling oxygen. By means of anæsthetics we can separate these two phenomena. An aquatic plant placed in etherized water ceases to absorb carbonic acid and emit oxygen. It however, remains green, and breathes as animals do, a phenomenon which existed before, but was hidden by the assimilation of the carbon; still, further back, we can encounter one of those phenomena long considered chemical and which nearly escape vital acts inasmuch as in the laboratory some of them can be reproduced without the aid of life. I speak of fermentations. These are produced by a microscopic fungus, which decomposes fermentable matter, nourishing itself with a portion, while the remainder forms a new product which stays in the liquid. These fermentations, in spite of their extreme tenuity and their inferiority in the organic scale, are susceptible of being stupefied by ether and losing their active power. We may place them with impunity in close contact with the liquid, but the latter remains undisturbed.

Thus, from the very bottom of the ladder, from the simplest protoplasm, and the most insignificant fermentation to the most elevated creature to be found on the earth, we find always the same characteristic and fundamental property of life, modified, it is true, to a degree which forces us to follow the thread of its diverse forms step by step, but always identical in substance, and invariably demonstrable by those infallible reactive agents, anæsthetics. Without this property there can be no life, or rather no active life, no exterior manifestations. With it, any plant or animal, no matter how simple in construction, develops, grows, prospers and reproduces itself. It is easy to see, therefore, that sensibility is the principal attribute of all organic beings, and in some way the cause of everything that takes place within us. If, as Condillac says, we should take an immovable and insensible image and endow it gradually with all our senses, it would soon rise from nonentity and begin to augment the sphere of its knowledge. By giving it the sense of hearing, we open that vast field of observation and reasoning which procures sound, but it could form no idea of the existence of matter, or of sunshine, or of taste. It could only conceive one thing, until put in complete possession of the other senses.

Intelligence, that precious gift which alone renders us superior to other creatures, is, therefore, nothing more than the result of our accumulated impressions, controlled one by the other, and we may even affirm that the man who has felt is alone capable of thought. The development of our minds should be adequate to the development of our sensibility, and in fact, it can be observed everywhere, that those persons whose senses are the most refined, possess the highest form of intelligence. I may even go so far as to parody the famous proverb and say to my neighbor; "Tell me what you feel, and I will tell you what you think."

Not so very long ago, as we have seen, Linnæus refused to admit of sensibility in regard to plants, saying that it was an attribute of the animal world only. An attentive investigation, however, causes us to reject such distinctions to-day. Let us even go further back, leaving behind us the lowest forms of organic matter, and see if any phenomenon approaching sensibility is to be met with. In a word, let us ask the following question: Is matter sensible?

Referring once more to Claude Bernard's definition of the term, "sensibility is the *ensemble* of all kinds of modifications determined in living beings by different stimuli," we find no possibility of its application to the properties of matter, for it distinctly states that the condition is an attribute of living beings only. But a mere definition should not arrest our investigation, for it is nothing more than the result of knowledge hitherto acquired, and as such admits of change. The substance of it all amounts to this; given a living being placed in immediate contact with matter, and the matter will act upon the being, producing sensation. But how do we know that the living being does not in its turn act upon the matter and modify its condition? I will even affirm that life does act upon certain substances, for fermentation is a positive proof that this is the case. If I place a sweetened solution of wine in contact with the air, a short time will suffice to develop therein millions of tiny living creatures proceeding from atmospheric germs. This fermentation increases with great rapidity, producing a chemical effect, so that after a certain time the sugar will be transformed into carbonic acid and alcohol. The presence, therefore, of life in the liquid served to modify the properties, and in this we see one of those strange occurrences where the so-called vital forces are so closely allied to chemical processes, that we hardly know whether the phenomenon is the result of the biologists' skill or the chemist's. Each of these *savants* have claimed it as their own, and with reason too, for chemistry and biology are twin sisters who can never quarrel.

When the sugar is once transformed into alcohol another organism appears, which, in its turn, determines the transformation of this substance into another, acetic acid, by means of an analogous fermentation. It is a remarkable fact, however, that while the chemist has, as yet, been unable to produce alcoholic fermentation by means of the action of matter upon matter, he can, on the contrary, easily determine the second without the aid of life at all. It is, therefore, the presence of these bodies which acts, and not the construction of the fermentation. It is not that life decomposes the liquid, but that the liquid decomposes itself when assimilated with certain agents. It is therefore sensible of their action.

Once *en route*, it is not difficult to multiply examples and to demonstrate that light, heat, electricity and all other forces which operate upon our sensibility, are uniform modifiers of matter. What is a photographer's negative but a glass plate sensitive to the action of light? Is not a piece of wire about which we pass an electric current sensible of electricity, inasmuch as it acquires thereby a new property, that of attracting a like piece of wire? It becomes, in fact, magnetic.

Heat, as we can observe every day, modifies bodies to such an extent, that beneath its influence they liquify and evaporate. All these facts demonstrate clearly that matter is sensible of exterior agents. According to the second part of Claude Bernard's definition, it possesses the "aptitude to reply to the provocation of these stimuli by means of modifications."

Consequently, universal attraction, that law which affirms that all bodies attract each other in direct ratio to their mass, and in inverse ratio to the square of their distance, is merely a simple and general way of expressing the sensibility of matter.

CONTRIBUTION TOWARD A NEW COSMIC HYPOTHESIS.

By Samuel J. Wallace.

Our familiar knowledge and ideas in astronomy relate generally to matter in large bodies, and in great numbers of small bodies, which now and then fall into the larger as meteorites. This seems to show a condition of slow centralization, as if to finally collect all matter, however far distributed, into a few large bodies. And a consistent conception requires in its plan, somewhere, a means of decentralization, or distribution of matter through space again, to form a closed system of action.

Gravic force as one of the interchangeable forms of kin-

etic energy also requires a starting place; some way by which the energy continually changed into mass motion and heat of bodies gravitating into each other shall be changed back again into gravic force.

I think the luminously hot gaseous nebula shows the earlier stages of these two required dispersions taking place together.

The fall of matter from space into central masses takes up just so much gravic energy. This is changed into mass motion and heat, so that on mechanical principles, each particle bears just enough force still to carry it back into space again.

This leads us up to the idea of the life of a particle in the universe, as being through an endless series of cycles of change from space into masses and from masses into space, each being, as it were, almost an eternity in duration, making a grand orbit, something like this:

Meteoric matter falls from space into planets and suns; planets fall into suns; suns grow continuously larger, accumulating the momentum of particles acquired in falling from space, as motion and heat; the heat of overgrown suns at last becomes so intense, from accretions and collisions, that it flies into a still higher form of repulsive energy, as gravic force, causing disruptive explosions; the particles, by this change into gravic force outward, receive a projectile force carrying them out into space again; and particles from space fall again into planets and suns.

This forms a closed cycle of action. The projectile and outward gravic forces may carry part of the particles forward into space till they become parts of other systems to run like courses; and part may be driven back at last to rebuild another system instead of that destroyed. Some might be driven back by the extra-force given others, and form nuclei of one or more suns. And the disrupted parts going in different directions might form a number of nuclei, having such dispersive motion as to carry them continuously apart, as in some reported cases.

The history of a nucleus having such an initial projection might be something like this:

I. It might pursue an interminable course; should this lead laterally near any region having matter in great quantity, it would be deflected to pursue a great curve, attracting to itself distributed matter within its reach, from gravitation.

II. The growth of a body pursuing a curved course would produce in it a rotary motion, which would be the resultant of the course and force of its own prior parts and those of its continued accretions, and of the combined attractions on its several parts of all matter passed, which of course would predominate on the inner side of its curved path.

III. Matter drawn into a moving body would come in curved lines and spiral courses, tending to form great rings and to produce planets, whose courses and velocities would be the resultants of the total averages of those of the various particles uniting to form each of them.

IV. Secondary bodies of large size would approximate primaries in the nature of their actions, falling in by slow degrees: those of long life as secondaries tending to eventual motion in one general direction, from having similar producing forces and from their actions on each other neutralizing conflicting equivalents; giving to each such position as its resultant velocity leads to, by union or separate course, together with revolution, and possibly secondaries to them.

V. Differences of inclination of orbits of secondaries may occur from the course of primaries having been at some time near regions having predominant quantities of matter to be drawn in on special sides, which unites to form bodies having their special courses; and, from analogous causes some smaller bodies might chance to have courses contrary to others.

VI. The four terms of orbital and rotary velocity, heat, and loss from radiance and from a resisting medium, would form a sum equal nearly to the energy of fall from infinity to the mean position of each body, qualified by whatever initial velocity and direction each particle may have had from its prior projections.

VII. The distance of each body from its primary would depend on its velocity in proportion to that which fall from infinity would produce; and all causes changing orbital into rotary motion, into heat and radiance, and into friction on a resisting medium would shorten the mean distance; but add to the velocity.

These I think are about the things which would occur, stamping the history of the system upon its internal peculiarities.

Now, does this sort of hypothesis come nearer accounting for the solar system than the original or present day forms of the "nebular hypothesis?"

I think that requires far too extravagant a conception of a common initial force taking possession of the matter thinly distributed through so immense a region as a globular space extending far out beyond the orbit of Neptune; and that it does not account for the variations of detail, nor for a final closed system of action, as does this.

I have no faith in this stuff about burnt out worlds, thinking that planets and suns grow warmer instead of colder as they slowly grow larger from fall of meteorites, as now going on.

Gravic force, which causes gravitation of bodies toward each other, probably has some resistance and loss in passing through large bodies; which would heat them and give ample source for all extra heat in the sun and large planets, and the interior of the earth; and would give ample time to geology for all its work. In fact, it may thus greatly increase the stores of heat beyond that given off by radiance, and that gained by falling from space; and so assist in forming the store for final dispersal.

The analogies of the other forces in passing through massive media seem to force us to expect such loss causing heat; and there is reason to suppose there is a slight resisting medium to matter in space: the dynamic equivalent of this loss of gravic force, in the life of the particle.

Without a resisting medium to matter in space it is hard to understand how matter can congregate into masses instead of always flying off again with equivalent velocity.

And it is equally hard without a resistance to gravic force in bodies to understand how gravic force can act to cause gravitation, or how the particles in a fixed body, radiating its force, can ever again get energy for dispersal into space.

But the arrangements may be so wonderfully balanced that the one propulsive gravic force may bring particles together from far space to form solid bodies and suns, and then when their course is run, store up energy in them to carry them back into space again, to go onward and build up new systems of glory.

The mountains of the moon, which have been called dead volcanoes, are simply the drop marks of great meteoric masses falling into the light meteoric dust forming in the outer part of the moon. They are similar in their peculiar forms to the rain drop marks familiar to geologists in sand-stones; and have the same peculiar raised rims and concavities, with the bodies which produced them still standing in their centres.

Some seem to have exploded like shells, sending masses in various directions tearing great furrows, some radiating across the whole face of the moon.

They may represent an enormous period, as the absence of wind and moisture would permit marks once made to remain until obliterated in a like way; water, if there, being a frozen dust, and if ever melted sinking into the deep porous mass.

AMERICAN CHEMICAL SOCIETY.

The regular meeting of the American Chemical Society was held Friday evening, May 6, Vice-President Leeds in the chair. Messrs. J. G. Mattison, Theo. Tonnelé, and Dr. Otto Grote were duly elected members, and Messrs. A. H. Van Sinderin and C. P. Sawyer as associate members. Mr. A. P. Hallock was proposed for election. The first paper on the programme was "On a Slight Modification of the Wilkinson Gas Eudiometer," by Mr. James H. Stebbins, Jr., S. B. Having found considerable difficulty in the manipulation of the instrument as described by Dr. Wilkinson, Mr. Stebbins succeeded in overcoming his objections by bringing the stopcock nearer to the Eudiometer itself. It is very difficult, in fact impossible, to properly explain the improvement without illustrations. At the conclusion of Mr. Stebbins' paper, Dr. C. A. Doremus very thoroughly explained the method of procedure used by Dr. Wilkinson in his working of the Eudiometer. This made the matter clearer, still the improvement by Mr. Stebbins was thought desirable.

The next paper* was by Dr. T. O'C. Sloane, "Note on the Purification of Baric Sulphate." The authon finds in order to obtain a precipitate of barium sulphate that will not run through the filter, a few rules must be observed. These he gave as follows: 1st. The solutiou must be barely acid. This end he secures by using cochineal, finding by its use that the neutralization can be more expeditiously and exactly performed than with litmus. 2d. The precipitant is added when the solution is almost up to a boil and kept at that temperature for some minutes. By following these two suggestions a heavy precipitate with a perfectly clear supernatent liquid will be obtained. In case any iron salts have been carried down with the barium sulphate, the precipitate is to be treated first with hydrochloric acid and secondly with sulphuric acid, but this process is open to some objections. It is therefore best to fuse the precipitate with sodium carbonate and a very little sodium nitrate and redetermine the sulphur. As an improvement, Dr. Sloane finds the following method quick and reliable: The sulphur is precipitated in the conventional manner with the previous mentioned precautions carefully observed. The solution is then decanted to the last possible drop through a filter paper; 5 or 10 c.c. of conc. hydrochloric acid are then added and the beaker held in the hand over a hot plate until the acid is brought to a full boil. It is allowed to continue so for a few minutes, then cooled and diluted. The liquid neutralized with cochineal solution, re-acidified and poured into the filter. By this manner a white and clean precipitate was obtained. Dr. Sloane immediately followed with a description of a new "Qualitative Test for Carbon Disulphide and Carbon Dioxide in Coal Gas." A piece of caustic potash, a few m. m. long, is added to ten or twenty c. c. of alcohol, into which a piece of potassium carbonate has been added. The alcoholic solution of potash is placed in a suitable absorption tube and a cubic foot or more of gas passed through it. It is then removed from the absorption apparatus and poured into a test tube. If the gas contains any carbon dioxide, an oily looking layer, nearly colorless, of a solution of potassium carbonate will underlay the alcohol, which latter will have acquired a reddish color. The alcoholic solution, which, if any carbon bisulphide be present, will contain potassium xanthate, is boiled and tested for hydrogen sulphide. Another method, is to add an excess of a copper salt, filter out the precipitated copper compounds and pour ammonia through the filter paper, when a highly characteristic yellow precipitate of copper xanthate will remain behind.

The fourth paper was by A. R. Leeds, Ph. D. Its title was "Upon the Direct Conversion of the Aromatic Amides into their corresponding Azo-compounds."

This paper was a sketch of the recent work which Dr. Leeds has been prosecuting in his laboratory at the Steven's Institute. It consisted, as described in the title, of the details incidental to the conversion of the different aromatic amides into the corresponding azo-compounds with the peculiarities of each commented on. Many of the hydroxylated compounds were also operated on by Dr. Leeds.

Mr. A. A. Julien followed with a very interesting paper "On the Chemical Contents of the Fluid Cavities of Minerals." Mr. Julien is the well known lithologist of the School of Mines in this city, and has a higher reputation in this specialty than almost any other scientist in this country.

He first gave a general outline of the history of the subject. It is only comparatively recent that any attention has been paid to these cavities, which are very minute in size and generally of a rounded shape, though sometimes following the outlines of a crystal, that is to say, the cavity is of the same shape as a crystal of the substance in which the cavity occurs. New York is, for many reasons, the best place to study this subject; for instance, a greater number of specimens find their way to this city. Among the substances found in these cavities are: water, carbon dioxide, nitrogen, sulphur dioxide, ammonia, fluorine, chlorine, oxygen, hydrogen disulphide, and rarely bituminous and light hydro-carbons.

Herkimer, N. Y., is a locality where the latter are frequently found.

Carbon dioxide is, however, the most interesting of these substances to the chemist, and it is also the one most frequently met with. It is found in some fifteen localities throughout the United States. One locality is known in New York State. These cavities are generally found in granites, granito-porphyries, hornblendic and other gneisses and in smoky quartz. The most characteristic feature of the carbon dioxide in the cavities is its remarkable expansive quality—so great that in touching it the warmth of the hand will completely vaporize the liquid compound. Mr. Julien has devoted special attention to the determination of the temperature at which the liquid expands and for that purpose has devised a form of apparatus to be used in such estimations. The piece of mineral containing the cavity is mounted on a microscopic slide and placed in the new apparatus, which consists of a long metallic box, with a small tube on the surface, to which a rubber tube is attached. The whole apparatus is placed in the microscope. On blowing into the rubber tube sufficient heat is obtained to cause the expansion of the bubble of carbon dioxide. Readings are made of the temperature at which the bubble disappears and also of the temperature at which the bubble reappears. Mr. Julien's results agree within two tenths of a degree Fahrenheit.

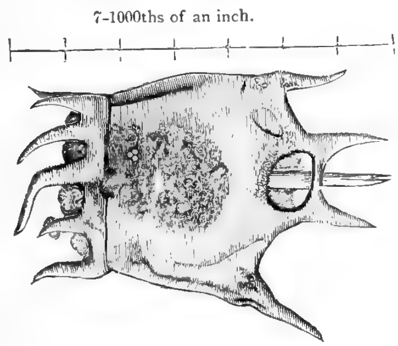
Thus by the ordinary method (Fuessi's) two results, 80.1 and 79.5 were obtained, while with the improvement six results were obtained as follows: 79.6, 79.4, 79.6, 79.5, 79.5 and 79.6. Mr. Julien also gave a very interesting description of "Reticular Fluid Cavity" in Topaz from Brazil, whose bubble was the largest ever discovered, being 2.28 m. m. in length. He also referred to the spontaneous motion observed in the bubbles and to the general bearing of the entire subject of the gensis and formation of rocks. M. B.

* I would acknowledge my indebtedness to Dr. Sloane for his kindness in lending me his original MSS.—M. B.

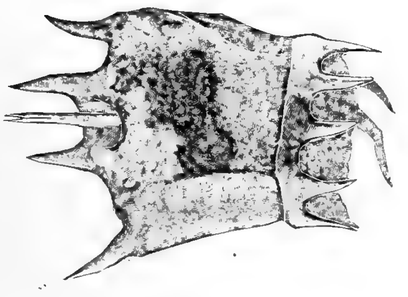
M. DUCHEMIN, the inventor of the compass with circular magnets, now adopted in the French navy, has lately devised, for correction of compasses, a system of magnetic compensators, in which magnetic bars of annular or circular form are used in place of the straight ones. These have the advantage of insuring much greater magnetic stability than straight bars, especially when lightning occurs in the neighborhood of the ship.

A NEW ROTIFER.

In a filtering of Hemlock lake water (Rochester's water supply) made in August of last year, I noticed a rotifer that at once struck me as different from any that I had before observed or seen described. On classification it proved to be a Brachionus, and a diligent search through the somewhat scattered literature on the subject has since failed to satisfy me that this form has ever been described.



DORSAL.



VENTRAL.

BRACHIONOUS CONIUM.

The Micrographic Dictionary uses the classification of Ehrenberg, while Carpenter in his work, "The Microscope and its Revelations," adopts that of Dujardin. While all classifications of the Rotatoria thus far made are in some ways unsatisfactory, that of Ehrenberg seems the least faulty, and according to it I find that this organism, by reason of having its rotary disk divided into two parts (*Zygotrocha*) and having a carapace, would show that it belongs to the family "*Brachionœa.*" There are five genera in this family. The Brachionus has one eye-spot and forked foot, and to this genus the rotifer unquestionbly belongs: "*Brachionus Conium.*"

Lorica irregularly truncate, slightly reticulated over entire surface except the collar carrying frontal spines; this latter portion has a hard vitreous appearance.

Ten frontal spines, the middle one on the dorsal surface longer than the balance and describing almost a right angle turn near its center to one side. This spine half as long as the carapace of the rotifer. Eye-spot prominent. No openings on dorsal surface of carapace.

Four posterior spines, one at either extreme side and one on either side of anal opening. Tail or foot, slender and bifid. Extreme length of rotifer including anterior and posterior spines, seven one-thousandths (7-1000ths) of an inch.

Unfortunately a dead specimen had to be used for the drawing, hence no definite description can be given of mouth parts for internal structure. The external appearance is, however, so strikingly characteristic as to serve all purposes of identification until the internal structure can be fully described. H. F. ATWOOD.

MICROSCOPICAL NOTES.

The subject of standard screw gauges was recently brought before the R. M. S., and the question of the accuracy of 50 duplicates, made for distribution, was discussed. Mr. Bevington considered "they were as near the standard as could be expected." Mr. Beck pronounced them on trial to be defective. It seemed to be conceded that the original "taps and dies" had been lost, but as Mr. Crouch thought that the present set of duplicates was sufficiently perfect for all practical purposes, we suppose opticians must rest and be thankful for what they can obtain. Considering the deterioration, which must occur from the wear and tear of the cutter, it is to be regretted that perfect accuracy cannot be given to the standard gauges issued by this society.

On the presentation of a paper by Mr. Shrubsole on the "*Diatoms of the London Clay,*" the President, Professor Martin Duncan, made the following interesting statement on the subject. He said that "those who studied this class of subjects would be greatly interested in the paper which had been brought before them; and no doubt had it been read before the Geological Society, there would have been considerable discussion upon it. The London clay had at the bottom of it large beds of pebbles; these were all water-worn, and clearly indicated an old shore. Just above this, on a sinking shore like it, would be precisely where they should exexpect to find diatoms. But the London clay just above this became a little more marine, and this fact would acccunt for their not finding these fresh-water forms there also. Then it should be remembered that the occurrence of diatoms was subject to great variations, and that they were always found in greatest abundance in the neighborhood of silicious rocks. As regarded their age, he thought there could be no doubt that they lived at the time of the Lower Eocene. There were, however, some peculiarities about the London clay, there being no other strata which were deposited under the same conditions, because it was not a reef deposit, but it positively told the story of an open estuary leading down to a very large river. This was one reason why they would not find the diatoms in similar deposits in Italy or Wales. It was not an uncommon thing to find that in other fossils the carbonate of lime was replaced by sulphide of iron. Phosphate of lime was often also replaced by sulphide of iron, and the interstices of other fossils were often found filled with the same substance, which was an exceedingly common mineral in the London clay. Silica was not the difficultly-soluble substance which it was formerly thought to be, so that its place could be as easily filled up by any other mineral which was less soluble than itself—from which consideration he thought the matter might be explained. But when they came to the question of antiquity, it was not so easy to give an opinion as to whether Count Castracane's diatoms in the Carboniferous series were with good reason thought to be diatoms. In the Tertiary of course they found them; but if Count Castracane's propositions hold good, we ought to be sure to find them in the intermediate series."

Mr. Shrubsole said Mr. Kitton's idea was that they were fresh water diatoms which had been washed down into the coal-beds.

The President expressed himself unable to accept such a suggestion.

LAST week the Whittaker Court Marshal was continued, and Dr. Piper of Chicago, was examined as an expert on Microscopy. In cross-examination questions were submitted to the witness on the construction of the Microscope, which Dr. Piper admitted were beyond his knowledge. One question related to the composition of the glass used for the construction of lenses for the Microscope.

Possibly few Microscopical experts could answer

questions on this point, and we would be obliged if any of our correspondents would furnish a few facts. We understand that some makers make use of a very soft glass, the surface of which becomes defaced in a short time: a dealer calls this "*spongy glass.*" We would like to know where the respective makers purchase glass for objectives, and its composition.

ASTRONOMY.

COMET (*b*) 1881.

Prof. Barnard, of Nashville, Tenn., announces the discovery of a comet on the morning of May 12, 1881, in R. A. $22^h\ 59^m\ 18^s$, dec. + $14^\circ\ 24'\ 30''$. An observation on the following day gave R. A. $22^h\ 58^m\ 52^s$, dec. + $14^\circ\ 36'\ 0''$, thus indicating a motion 24^s in R. A., and $11''$ in Dec. The comet is reported as very faint.

ON THE USE OF THE ELECTRIC TELEGRAPH DURING TOTAL SOLAR ECLIPSES.*

If we suppose a single observer to be prepared for the observation of all the total solar eclipses of a century, we shall find that the entire amount of time during which he may contemplate the totally eclipsed sun will not differ much from an hour. We may be sure then of the expediency of any scheme whereby the rare moments of these eclipses may be utilized to their utmost extent. If such scheme is devised, two important results are likely to follow.

(1.) Economy of the sum-total of energy in any particular line of solar research.

(2.) A consequent enlargement of the means of research in other directions.

The general conception of the scheme proposed in this paper may be very briefly stated: Suppose a station to the east and a station to the west on the line of any total eclipse, as widely separated as practicable, and equipped for similar observations of discovery during the progress of the eclipse; the method proposes the electro-telegraphic transmission of important observations made at the western station to observers at the eastern station, with due speed for their verification or rejection when the lunar shadow reaches the latter station.

For illustration, consider the next total eclipse,—that of 1882, May 16. In detail, the particular advantages in connection with this eclipse seem to be about these:

(1.) The path of totality is almost exclusively on land. Central eclipse begins in West Africa; the line of totality passes to the north-east, crossing Upper Egypt and the Nile at El-Akhmym; thence over the Red Sea, crossing the Tigris a few miles to the south of Bagdad; then passing a little to the south of Teheran, it traverses Central Asia, and leaves the Asiatic Continent somewhat to the north of Shanghai.

(2.) Though not generally through the inhabited regions of the globe, the path of totality lies through several inhabited regions which are widely separate, viz: Egypt near the Nile, Central Persia and Eastern China.

(3.) These regions are inter-connected by telegraphic cables and land-lines.

Now, we will suppose that an important observation of discovery is made at El-Akhmym,—an observation of an intra-mercurial planet for example. Between 40 and 45 minutes of absolute time elapse before totality comes on at Teheran. During this interval the observer at El-Akhmym will have an abundance of time for transcribing the apparent magnitude and the precise position of the new body, and transmitting the same to his fellow-observer at Teheran several minutes before the lunar shadow reaches him. The latter observer will then have leisure to proceed with the setting of his circles, the verification of their readings, and the pointing of his instrument to the precise part of the heavens indicated. He may then be able to see the suspected object before the eclipse becomes total. He may also decide upon a neighboring star for comparison with the planet, and thus obtain a very accurate determination of its position. The observer at Teheran should also be prepared for an independent search for the suspected planet, in the event of receiving a negative message from the observer at El-Akhmym.

The observation at El-Akhmym should also be transmitted to Shanghai, (reached by the shadow more than two hours after totality at Teheran), for independent verification at that point. We might thus observe the result of nearly three hours' motion of the planet,—which we might reasonably expect to give important data in regard to its orbit about the sun. Of course, the result of observation at Teheran would also be transmitted to the observer at Shanghai.

It was my intention primarily to have considered the total eclipse of 1882 merely as an illustration of the method proposed. Further investigation, however, seems to show that it is at least one of the two most favorable eclipses during the present decade, if not during the present century.

WASHINGTON, *May* 18, 1881. W. C. W.

*Abstract of a paper by D. P. Todd, M. A., presented before the American Academy of Arts and Sciences, Jan. 12, 1881.

COMET (*b*), 1881, BARNARD.

To the Editor of "SCIENCE:"

On the morning of the 12th, while sweeping the eastern sky in search of comets, at about three o'clock, an object entered the field of my telescope which I strongly suspected was a comet, as I did not know of any nebula near its place. I at once secured its position relative to *α Pegasi*, it being in the field with that star. Its position at seven minutes past three o'clock was:

$$\text{R. A. } 22^h\ 59^m\ 18^s$$
$$\text{Decl. } + 14^\circ\ 24'\ 29''$$

The object was watched at intervals until about four o'clock, when daylight prevented further observation. During this time no motion was detected. Wishing to confirm the discovery by a second observation, before announcing it, I waited until the following morning, when upon turning my telescope to the point where the object was seen, I found it had disappeared.

No doubt now remained in my mind of its cometary character. I began a search to re-discover it. After sweeping for some time in the immediate neighborhood, I found it again as day-light was whitening the sky. It was very close north following *α Pegasi*. The object was then only visible when the bright star was obscured by a part of the ring suspended in my eye-piece. It followed the star by six seconds and was therefore in R. A. $22^h\ 58^m\ 52^s$. I estimated the difference of declination between comet and star, and found it to be in north declination $14^\circ\ 36'$. No doubt now remaining that it was a comet I telegraphed its position to Professor Swift, Director of the Warner Observatory at Rochester. On the morning of the 14th I again began a search as soon as the object had risen above the horizon, but it could not be found. At first I attributed my not finding it to its low altitude and the bright moonlight. The search was continued until daylight, and I was deeply mortified at not finding any trace of the object. In the morning telegrams from Rochester and Boston announced failure to find it at those places.

A short search this morning, when the sky had cleared, at about day-light, resulted no better than yesterday morning. The object on the 12th was slightly smaller than Swift's last comet, which I had been observing on the 11th, and was probably a little brighter. On the 13th it

appeared very faint. This I attributed to its proximity to the bright star.

I shall continue the search for it. The moon will leave in a few days and I then hope to be able to see the comet again. E. E. BARNARD.

May 15, 1881.

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

To the Editor of "SCIENCE:"

I should have attempted a reply to the restrictions of Mr. Dopp before this time if I had not had my hands too full of other work, but lest any might think I have nothing to say if an answer of some kind did not shortly appear, I will ask the favor of a little space, and first I entirely disclaim the pretension of undertaking to reconstruct Physical Science which Mr. Dopp seems to impute to me, and whatever was put forward as new was only hypothetical, and perhaps I was not guarded enough in specifying it as such. Yet there is more that may be said for some of the statements made than appears in those papers, which were very brief and did not pretend to give references. But now if I shall deal with the subject of internal and external energy which is attacked in the last part of Mr. Dopp's paper, it will save saying very much about the first part.

Mr. Dopp quotes from Maxwell's works on Heat, and says they disprove and invalidate all my calculations. But it will probably be allowed to hear Maxwell in 1875 against Maxwell of 1872:

"In 1860 I investigated the ratio of the two parts of the energy on the hypothesis that the molecules are elastic bodies of invariable form. I found, to my great surprise, that whatever be the shape of the molecules, provided they are not perfectly smooth and spherical, the ratio of two parts of the energy must be always the same, *the two parts being in fact equal.*" He also says a few lines beyond when speaking of the researches of Boltzmann, he "makes the whole energy of motion twice the energy of translation." See Nature, volume 11, p. 375. This language justifies my work and my calculations are not invalidated. What is to be understood by $E' - E = \epsilon$, is their difference and not a ratio, and the expression in the paper is wrong, but there is nothing in the paper that depends for its correctness upon any mathematical expression in it, whether it is right or wrong, and cannot be raised against it. That is to say, there is nothing in the first paper that is a deduction from any mathematical work given.

As to my definition of ether as not matter, again Maxwell is quoted against me, and I will therefore again quote Maxwell in my favor. "According to Thomson, though the primitive fluid is the only true matter, yet *that which we call matter is not the primitive fluid itself but a mode of motion of that primitive fluid.*" See Art. *Atom* Enc. Brit., 9th Ed. The italics are mine, but if it does not plainly make a distinction between ether and what we call matter, then I don't understand it. But I claim more, that to call ether the primitive matter is to call two different things by the same name, and my first paper was a protest against that. Newton's law of Universal Gravitation states that "every particle of matter in the Universe attracts every other particle of matter," and until it is discovered that ether possesses this property of attraction, I hold that the name *matter* should not be applied to it. If, however, any one thinks it to be a proper use of words, I shall not quarrel with him, only when he talks to me of matter I shall need to ask whether he means gravitative matter or non-gravitating matter. As for the objection that I use the term density applied to ether and am therefore to be held to what is implied in the word; any one who undertakes to express a new conception must either employ words that have some fixed meaning or else coin some new word which in its turn must be defined with old words. So while the term density conveys my meaning in a tolerable way, I do not wish to have it imply that density in ether and density in matter are identical. In the same article on Atoms, Maxwell says concerning the vortex-ring theory: "We have to explain the inertia of what is only a mode of motion," and this is in strict accordance with all I have written about it.

We do know that the motions of atoms set up corresponding motions in the ether, and it is not difficult to perceive how it may happen, though the particular mechanical conditions may not all be known. *Assuming that the conditions are mechanical,* then the analogy of the vibrating tuning fork is not so far fetched as it might be. I do not see the necessity for my being held to atoms combining in only one plane. It is as easy to see that three or four or more could all unite at the same place so as to form a radial structure or a triangular one when one of the two represented in the diagram should swing round 120°, which, so far as I can see, would not imperil its stability at all, and it then would be in position for another similar atom to unite with each, and so on almost any kind of a geometrical solid made. But I did not intend to assert at all that in this hypothesis there was anything more than an idea. I am not ignorant of the molecular form of ordinary matter, but my assumption was that the molecular form was due to its vibratory energy, and, consequently, I was mostly treating of atoms, and the statement was made that at or near absolute zero the chemical affinity was *nil*, and hence dissociation. This is plainly the case if chemism is due to heat vibrations, but it is corroborated by mathematical calculations. In a paper read before the American Academy, in February last, by Mr. D. E. N. Hodges, of Harvard College, but which has not yet been published, the same conclusion is deduced from thermo-dynamic considerations, namely, that at absolute zero "there can be no cohesion of molecules, and probably the same for atoms; it is the temperature of dissociation." Mr. Dopp quotes from Professor Tait what he knew about the phenomena of vortex-rings, but since Mr. Dopp's paper was written he has probably heard of some more phenomena of vortex-rings. See "SCIENCE," April 16th.

As to the paper on Atoms as forms of Energy the *idea* is not mine, but Thomson's, and whether or not the method therein shown of computing atomic weights is mathematical jugglery, as Mr. Dopp calls it, all I have to say is, I did not stake anything upon it. I thought if matter is a form of energy, the fact should appear in atomic weights, and so I made the calculations and published them, and if anyone thinks they signify nothing, why I will not quarrel with him. After so long a paper finding fault with anything I had written, it was something of a pleasure to read that he thinks my theory can be made "a fair working hypothesis to explain adhesion, cohesion, and even crystallization,—surface tension of liquids and capillary attraction, and possibly those of osmosis, dialysis and occlusion."

This is not an unworthy stock of phenomena to explain, and if what I advanced can not be made to do all I proposed to have it do, I might be content if it explained in a fair way any one of the above phenomena.

A. E. DOLBEAR.

COLLEGE HILL, Mass., *May* 10th, 1881.

To the Editor of SCIENCE:—

As two of your correspondents, Mr. A. E. Dolbear and Mr. George W. Rachel, have adversely criticized certain points in my article in the April 9 number of "SCIENCE, and as I still consider my position as stable, I must request a limited space to reply to these gentlemen.

The main difficulty seems to be that I have gone

counter to certain authors whom they are disposed to consider as authorities. But, in my view of the case, Science has no authority, except the authority of facts, and theoretical views are always fair food for criticism. Mr. Dolbear quotes from Clausius to the effect that "all heat existing in a body is appreciable by the touch or the thermometer; the heat which disappears * * * * exists no longer as heat, but has been converted into work." Heat is undoubtedly appreciable, but not necessarily measurable, by the touch or the thermometer. As the heat capacity of any substance increases its temperature effect for equal volumes of inflowing heat diminishes, so that the thermometer fails to indicate the exact quantity of heat which a substance receives in passing through a fixed range of temperature. It is customary in late authors to speak of this apparently lost heat as converted into work, or, in other cases, to speak of it as changed from actual into potential energy. This is, undoubtedly, a very convenient way of getting around the difficulty; but, with all due deference to the distinguished writers who advance this hypothesis, I venture to question if it is a strictly scientific way. To come plump up against a difficulty in your path, to explain this difficulty by a nicely sounding word which explains nothing, and then to go swimmingly on, enables one to get over a great deal of ground in a short time; but it is very apt to leave stumbling blocks for those who come after.

I should certainly like to see a precise definition of the word "work" in this connection. Heat produces a certain effect. That effect is called work. But the important question remains, what has become of the heat? It was a motion. Has it ceased to be a motion? If so, then motion can cease to exist. Yet I hardly think any scientist will admit such a possibility. But if it has not ceased to be motion, where is it? Is the word "work" advanced as a name for some new mode of motion? Whether it is or not, however, it fails to explain what has become of the heat. We meet with a like difficulty in the theory of the conversion of actual into potential energy. Actual energy we can readily comprehend; it is the energy of the motion of masses. But what is potential energy? It is a possibility of mass motion. A body rests upon the earth. It cannot possibly descend further. It has no potential energy. A body is suspended in the air. It may possibly descend further. It has potential energy. Potential energy then, is possibility of motion. Actual motion has been converted into possible motion. If this amounts to more than the explaining of a difficulty by a meaningless phrase, I should certainly be glad to have some one scientifically explain the explanation. I must quote from my former article: "Motion is motion and cannot possibly be or become anything else." Actual motive energy cannot cease to exist, and be replaced by an abstract possibility of motion, called potential energy.

In regard to Mr. Rachel's remarks on my views respecting variation in heat capacity, he must permit me to correct his quotation. He quotes me as saying: "Temperature and heat are very different things." I find my expression to be: "Temperature and *absolute* heat are very different things." There is a considerable difference of meaning between these two expressions, which it would have been well for him to give me credit for. The main difficulty in the minds of both my critics seems to be a somewhat confused idea as to what constitutes heat. Mr. Dolbear claims that the free vibration of molecules is not heat. In this he certainly disagrees with most authors. Mr. Rachel states that "latent heat is not heat." He intimates that it is work, but will he be kind enough to explain scientifically just what work means in this connection? He says further, "Water does not contain more heat than ice at 32°; it contains * * * more motion, but not motion of the heat kind." Of what kind then? "Nor is it true that as density diminishes the heat capacity increases." The heat has disappeared as heat, "but it nevertheless exists in the gas as a greater range of mobility."

We here get his definition of "work." It is "motion, but not motion of the heat kind;" it is "a greater range of mobility." Motion, then has not ceased to exist, and we have been splitting hairs about nothing. It is molecular motion, but not the special mode of motion which he calls heat. Yet it would be well to bear in mind that scientists are somewhat indefinite in their ideas as to just what mode of motion does constitute heat. In one case they speak of radiant waves as heat, in another as local molecular vibrations as heat; in a third, of the free motions of gas particles as heat, and in a fourth, of motive influences which cease to affect the thermometer as heat, for what else is meant by absolute heat? The *authorities* certainly consider that heat continues to exist as heat in the case of increased heat capacity, when they assert that specific heat varies with variation in the temperature of substances. Thus it seems that all motive influences of which we become aware in matter, outside of gravity, electricity, magnetism, light, chemism, and mass motion, are grouped together as heat, their varying conditions being simply pointed out by qualifying adjectives. The phrase, "Latent Heat," has by no means gone out of use. Sir William Thomson, in the last edition of the Encyclopedia Britannica, considers it necessary to still retain it. In fact there are various modes of motion, some centrifugal, others centripetal in their effects, so closely related to ordinary heat, that it has proved more convenient to consider them as special heat conditions than to devise separate names for them.

Mr. Rachel is still more decisive in regard to another portion of my article. He says, "Mr. Morris's conception of the action of gravity is still more erroneous. This gentleman says, 'the earth must fall towards the body with the same energy that the body displays in falling towards the earth'! Now the two fundamental laws of gravitation, as discovered by Newton, are attraction acts in direct proportion to mass and in indirect proportion to square of distance. The statement of Mr. Morris is therefore absolutely false."

Perhaps so, yet I hardly think that Newton himself would have so absolutely denied my proposition. Let us suppose the falling body to be increased until it equals the earth in weight. What would follow then—would not gravity cause them to approach each other with equal energy? Their attractive pulls upon each other would be equal, and therefore the effects of these pulls must be equal.

If, however, the falling body be greatly decreased in weight, this may seem to some to change the elements of the problem. Yet it can readily be shown that difference in weight makes no difference whatever in the result. We must not look upon the earth as fixed and the falling body alone as movable. They are both freely floating masses, each capable of yielding to any exterior impulse. The size or weight has nothing to do with the question. If an atom and the earth be side by side, and be attracted by a distant mass with the same vigor, they must move with equal energy towards it. Yet an energy which would give the atom excessive speed would produce an inappreciable effect upon the earth.

Suppose, for the sake of illustration, that the falling body weighs one pound and the earth one million pounds. Then the falling body will attract each pound of the earth's mass with a vigor dependent on its distance, and be attracted by it with equal vigor. To reach the whole attraction of the falling body we must add together this million of separate attractions. But, in like manner, to get the whole attraction of the earth we must add together its million of separate attractions. The body exerts a separate attraction upon each pound of the

earth's mass. Each pound of the earth's mass reacts with an equal vigor of attraction upon the body. We must add all these separate attractions together to get the whole sum of attraction in either case, and these whole sums are necessarily equal. The body, therefore, attracts the earth with as much vigor as the earth attracts the body, and necessarily, therefore, they must approach each other with equal energy. Of course not with equal speed. Under the above supposition their respective weights were as a million to one, and a million pounds falling one inch would be equivalant to one pound falling a million inches. Their acceleration in speed must likewise, in both earth and body, obey the law of gravitative acceleration.

It is well, therefore, to bear strictly in mind, that in gravitation, as in every other form of force, action and reaction are always equal and opposite.*

CHARLES MORRIS.

2223 Spring Garden street, Philadelphia.

*In my previous article, above referred to, there is a typographical error, which slightly confuses the meaning. On page 167, line 49, the phrase "this force is increasing," should read, "this force is unceasing."

PRIMEVAL ROTATION AND COSMICAL RINGS.
II.

To the Editor of "SCIENCE":—

Prof. A. Winchell, recounting the history of formation of the solar system from a sphere of incandescent gas, says: "The cooling and contraction of this vapor inaugurated a rotation." [1]

Matter is governed by law, hence the ball of gas must have obeyed laws governing gases. Men have detected several laws of nature, while doubtless there are others eluding research. The globe of gas was dominated by known or unknown laws; if by unknown, no scheme of planetary evolution can be outlined; by known, hypotheses are tested by their application. There exists a doctrine, the Nebular Hypothesis, and we take it for granted that its advocates conceive the gaseous sphere to have been wrought by known laws.

But no law of nature yet discovered is able to cause a sphere of gas to rotate.

Contracting by cooling did not begin rotation, for, by dynamic laws, the mass was not hot, but cold. If hot, contracting would not cause rotary motion, but would give rise to two motions, centripetal and peripheral, both radial instead of circular. The heaviest atoms, gravitating towards the centre, would displace the lightest towards the circumference.

Repulsion did not exist; this force can only obtain in matter *not* dissociated. Repulsion causes dissociation and vanishes, gravity reasserting dominion. Hence, repulsion is more ancient than that gravity which caused the mass to develop a solar system; else the first state of matter was in dissociation.

These things are unknowable; therefore, with adherents of the hypothesis, we dismiss repulsion, leaving the mass subject to no known energy but gravity. If repulsion did act it could not cause rotation. Gravity could never cause the ball to turn; it would bring every atom to a rest. The whole mass would arrange itself in concentric strata, whose distance from the centre would depend on specific gravity. Calm would ensue unless pressure was sufficient to force atoms within range of chemism. Chemical reaction would have no power to start axial revolution. It would evolve heat, repulsion and temporary expansion, which, waning, would leave the mass smaller through combination, no sign of rotary motion having appeared. The mass extended half way to α Centauri, it being equal in mass to the sun. Helmholtz has shown that if the matter in the solar system expanded to Neptune, "it would require several cubic miles to weigh a single grain."[2] But the same matter filled a sphere whose radii were half the distance of the stars in length. Estimation of its tenuity indicates that a space as large as the moon only contained a grain. Yet it was "intensely heated."[3] It is not known how many atoms make a grain; counting them by the million, they were yards apart, in frigid voids—hot! Obeying gravity, they descended with slowest conceivable motion; at no point in their fall displaying tendency to move in arcs of circles at right angles to their radial movement, which they must do to begin rotation in the cosmic sphere. In the present state of knowledge, judging from laws at work in the Universe, it can be safely asserted that the ball had no rotary motion. Ignoring these considerations, we will assume with Winchell that it was in revolution.

"The cooling and contraction of this vapor inaugurated a rotation which was inevitably accelerated to such an extent that a peripheral ring was detached which became a planet. The same process continued and other rings were detached which became other planets in due succession. Similarly, the planetary masses detached rings which became their satellites."[4]

Conceiving the mass to have cut loose from 61 Cygni and other cosmic masses; admitting cooling, contraction and acceleration, then the sphere would be unable to cast off by any law of nature hitherto discovered, the least particle, to say nothing of a massive ring. The ball had dwindled to the orbit of Neptune, acquiring such velocity as to no longer remain intact, so it cast off equatorial matter enough to form that planet.

The rate of motion on the equator was only 3.36 miles a second; and a vacuum as made by Crookes is as a solid compared with the density of the ring; yet Neptune's mass is nearly 102 sextillions of tons[5]. The material, being exterior, was of the lowest specific gravity of any in the mass; thence its volume was enormous; so great as *not* to be peripheral. The word periphery alludes to the surface, and Winchell says the ring was peripheral. It was not,—it was formed of gas torn up from a depth of hundreds of millions of miles, in order to secure substance sufficient to form Neptune. If not,—the mass was piled above the level of the equator, an impossibility, as gravity would bring it down. As soon as force raised a line of atoms above the equatorial level, around the ball, the next line of atoms below would ascend, then the next, and so on. The poles would depress causing the mass to assume lenticular form. This would retard rotation, allowing central attraction to regain control, bringing the mass to a sphere as in the beginning. This oscillation must take place so long as the mass remained a gas. Should it become fluid, then the alternations would be between a sphere and spheroid, and the mutation would obtain until solidification sets in. No atom at any period had power to overcome gravity, the stability of the mass being assured by inhering laws. The mass of the solar system, the mass of any planet, the direction and velocity of the planet's original motion, determine what orbit it shall traverse.

The orbit of Neptune is determined; it makes regular revolutions, hence the centre of the assumed ring that formed it, when abandoned coincided with the present track of the planet's centre. Therefore the ring was not detached when the mass was lenticular, for its edge then extended far beyond where Neptune now revolves; if it had been the planet would now describe our orbit much *farther* from the sun.

The mass reached the present path of Neptune when spherical, and that world was thrown off where it now makes circuit, the mass being a sphere when it parted with its first ring.

[4] Geology of the Stars, p. 279.
[5] Chambers' Astronomy, p. 898.

Then a segment half way to Uranus was torn away entirely around the ball, and the rupture took place along the chord of the arc. A section of this ring would be flat inside and curved outside; else a ring lifted out of the equator quite around the sphere, whose sections were circular, leaving concave walls of gas in north and south latitude. Neptune would condense somewhere on a line in the centre of gravity of the ring. In either case the orbit of the first world would be *nearer* the sun than now. It could not have been thrown off the surface, as there was not material enough; nor from the edge of the lens-shaped mass, nor from beneath the surface of the sphere, for from either place the orbit would not be where it is. It could not have been cast off at all. EDGAR L. LARKIN.

BOOKS RECEIVED.

THE HUMAN BODY.—An Account of its Structure and Activities and the Conditions of its Healthy Working. By H. NEWELL MARTIN, D.Sc., M.A., M.B. Henry Holt and Company, 1881.

This book is the fourth of the "*American Science Series*" of manuals prepared under the direction of Messrs. Holt and company, and will be found of equal value, as a popular guide to the subject treated, to the three works which preceded it. It is a reliable work, being compiled from the best authorities, and is not intended for specialists, but for general readers and students.

In an age when the Physician is called upon to explain to his patient, the *raisen d'etre* of the treatment suggested, and even to describe the peculiar condition of the organs affected, some knowledge of Human Anatomy and Physiology appears essential to those who desire to act as consulting physician in their own cases.

To meet such a demand for a popular work on the human body, Dr. Martin has prepared the present volume, which is free from technicalities, or scientific terms requiring interpretation. The reader has the advantage of one hundred and sixty-five excellent illustrations, and as Dr. Martin's style of writing is both clear and comprehensive, the task of the reader is an easy one.

The earlier works of this series have been reviewed in "SCIENCE" and comprise the following manuals: *Astronomy*, by Professors Simon Newcomb and Edward S. Holden: *Botany*, by Professor C. E. Bessey: *Zoology*, by Professor A. S. Packard, Jr.

OSTEOLOGY OF SPEOTYTO CUNICULARIA Var. Hypogæa, and of Eremophila alpestris, by R. W. SCHUFELDT, U. S. A.—Extracted from the Bulletin of the U. S. Geological and Geographical Survey—Washington, Feb. 11th, 1881.—Four full page illustrations.

ABSTRACT OF TRANSACTIONS of the Anthropological Society of Washington, D. C., with the annual report of the President.—For the year ending Jan. 20, 1880, and for the second year ending January 18th. 1881. Prepared by J. W. POWELL.—Washington, 1881.

THE TWELFTH ANNUAL REPORT of the American Museum of Natural History—Central Park, New York City—Dated February 15th, 1881.

REPORT of the Cruise of the U. S. Revenue Steamer *Corwin* in the Arctic Ocean, by Capt. C. L. HOOPER, U. S. R. M,—November 1, 1880—Washington, 1881.

REPORT of the Director of the Detroit Observatory of the University of Michigan—October 1, 1879, to January 1, 1881, Ann Arbor, Michigan, 1881.

ABSTRACT of some Paleontological Studies of the Life History of Spirifer lævis H. by, Professor H. S. WILLIAMS of Cornell University, Ithaca, N. Y.—Reprinted for American Journal Science.

OBSERVATIONS on Jupiter by L. TROUVELOT—Presented March 9th, 1881.—Reprinted from the proceedings of the American Academy of Arts and Sciences.

PROCEEDINGS of the U. S. National Museum, 1881. Check List of Duplicates of Fishes from the Pacific coast of North America (221 Species) distributed by the Smithsonian Institution in behalf of the United States National Museum.—Prepared by DAVID S. JORDAN and PIERRE L. JOUY.—April 13, 1881.

DESCRIPTION of a new species of Squalius (Squalius aliciæ from Utah Lake, by PIERRE LOUIS JOUY.

DESCRIPTION of a new Gobioid Fish (Othonops eos) from San Diego, Cal. by ROSA SMITH.

ON a Duck new to the North American Fauna, by ROBERT RIDGWAY.

ON Amazilia yucatanensis (Cabot) and A. cerviniventris, Gould, by ROBERT RIDGWAY.

DESCRIPTIONS of new species of Fishes (Uranidea marginata, Potamocottus Bendirei) and of Myctophum crenulare, J. and G.—by TARLETON H. BEAN.

NOTES on the Fishes of the Pacific Coast of the United States by DAVID S. JORDAN and CHARLES H. GILBERT.

In this paper descriptions are given of 109 species of fishes known to occur along our Pacific Coast between the Mexican boundary and that of British Columbia, with notes on the distribution, habits, size, value, etc., of each species, in advance of the publication of a general descriptive work.

AMERICAN KINDERGARTEN MAGAZINE.—Edited by Emily M. Coe, Bible House, New York.

We have pleasure in recognizing the sterling merit of this excellent little Monthly, a leading feature of which appears to be an attempt to popularize science in a form suitable for children. The present number contains articles introducing the young readers to the best methods of classification of the Animal Kingdom. The journal is in its third volume, and is sold for one dollar a year.

NEW APPLICATION OF THE SUB-PRODUCTS OF COAL-TAR.—Mr. Sanders, of St. Petersburg, has succeeded in producing from the heavy oils of coal-tar, a new substance which, in many cases, takes the place of india-rubber with advantage. It is prepared in the following manner. A given weight of a mixture in equal parts of wood-oil and coal-tar oil, or of coal-tar and hemp-oil, is heated for several hours, at a temperature of about 318° Fahr., so as to disengage the injurious substances and increase the viscosity of the mass, until it may be drawn out in threads. A second quantity, equal to the former, of linseed-oil, preferably thickened by boiling, is now added, and also from one-twentieth to one-tenth per cent. of ozocerite with a little spermaceti. In the meanwhile, the mass is kept at a uniformly high temperature for some hours, when from one-fifth to one-half part of sulphur per cent. is added, after which the product is moulded or otherwise worked in the same manner as india-rubber. The proportions of the three oils named above may be varied so as to obtain a harder or more elastic substance, as may be required. The product is elastic and tenacious, standing the weather better than india-rubber, and is not deteriorated by great pressure or a high temperature. It is said to be specially suitable for the insulation of telegraph wires, and may be employed alone or mixed with india-rubber or similar resinous substances.

ELECTROLYSIS.—Mr. E. F. Smith finds that a black hydrated oxide, Ur_3O_4, is precipitated when a galvanic current is passed through a solution of uranium acetate, formate, or nitrate.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at

TRIBUNE BUILDING, NEW YORK.

P. O. Box 3838.

SATURDAY, MAY 28, 1881.

In his recent address to the Royal Microscopical Society of London, the President, Dr. Lionel S. Beale, F. R. S., introduced some interesting facts relating to the present limits of microscopic vision, and indicated the advance that may be anticipated for the future in this direction.

Within five years it has been often asserted by those who make the Physics of the Microscope their special study, that the limits of microscopic vision had been almost reached by modern objectives, and that further advance was barred by insuperable difficulties. Since this time the record of progress contains numerous instances of advances made beyond these barriers which authorities considered until now insurmountable. Dr. Beale claims that "he only who is quite ignorant of the many and great improvements made in our methods of research, and in the instruments required for investigation, would think of fixing any limit to the advance of microscopical inquiry."

With improved instruments, the Microscopists have discovered improved methods of preparing objects for examination, and subtle agents united with the most delicate manipulation are now employed to develop structure, requiring the highest power of microscopic definition and amplification. We remember with Dr. Beale the time (within ten years) when in many branches of inquiry it was truly said that the optical instruments were in advance of the methods of making examinations, when our magnifying powers were higher than we could use, without losing, rather than gaining, as regards the definition of delicate structure. All this has now changed; the power of definition of objectives has been more than doubled, but the Biologist, in his investigations, anxiously demands higher powers and more perfectly corrected objectives.

Until recently the Histologist was satisfied with powers of five to six hundred diameters. Dr. Beale, in his recent address, states: "Our present limit of observation in investigations on the structure and action of the tissues of man and the higher animals, in my opinion, includes the use of magnifying powers of 2000 diameters. Objects considerably less than the hundred-thousandth of an inch can be studied with advantage, but how much less than these dimensions cannot, I think, be determined with accuracy at this time; for so much depends upon the character of the object, and a number of small points of detail as regards mode of examination.

But in other departments of Microscopical research our present means of investigation enable those familiar with the requisite methods of inquiry to demonstrate characteristics of structure far more intricate and minute than the above remark would infer. Various modifications of immersion lenses and in immersion media have greatly contributed to advance our knowledge of structure and action in the lower forms of life, and there is every reason to think that, as time goes on, methods of observation will be still improved and new methods discovered."

Another aid to perfect Microscopy is Photography, for by its use "things dimly seen by the eye may be very distinctly and correctly delineated, and with a perfection of accurate detail which a few years ago we should not have supposed possible." In this direction Dr. Beale states that "in all probability the application of photography to investigations upon minute structural details will be carried far beyond anything yet reached, although it is really wonderful how much has been achieved up to this time."

It will thus be seen that a variety of circumstances is steadily leading the way to what may be termed A NEW MICROSCOPY.

Both the Microscope and objectives, as also methods of manipulation, are being *revolutionized*, producing entirely new results. Even a new style of literature of the subject is developing. As far back as June, 1875, the editor of this journal, in a paper prepared for *Popular Science Monthly*, then foreshadowed this change. The article was headed, "*The Microscope and its Misinterpretations.*" A happy satisfaction then reigned among Microscopists, both with their instruments and their work, and the article was criticised as an assault upon the integrity of Microscopical research. It is some satisfaction to the present writer to find that those who then came forward as champions of the perfect microscopical work of that day, are now the most active leaders of the *new reform.* We refer to Mr. John Phin, the present editor of *The American Journal of Microscopy*, who can claim the honor of having established the first successful microscopical journal in the United States, and Professor J. Edwards Smith, of Cleveland, the author of

the recent book "How to see with the Microscope," a work which is a valuable addition to Microscopical Literature; both wrote articles against "*The Misinterpretation of the Microscope.*" In that article we gave very strong illustrations of the "*misrepresentations*" referred to, but the paper was written some years in advance of the present developments, which have made the case much stronger. The disputed resolution of the "Podura" scale was then quoted as an instance of an objective giving two distinct resolutions of an object, one of which was clearly an erroneous one, but who would have then anticipated that the spherules on "*Angulatum*" which we have for so many years religiously regarded as the true ultimate resolution of that diatom, would prove to be an illusion? While to make the case more complicated, Professor E. Abbe states that "while it is not my opinion that the *Angulatum* valve is composed of spherules, yet even if such should exist, they would not have a different effect."

Thus "*The Misinterpretation of the Microscope*" under certain conditions, is no myth, but an admitted fact; we welcome then the improvements which shall at least partially remedy the evil. The high angle objectives of the present, although far from perfect, give great hope for the future, and we trace in Professor Smith's work, to which reference has been made, the advent of a higher intelligence among Microscopical workers. This new spirit of progress is well described by Dr. Beale when he says, the Microscopist, like the Astronomer, is ever longing to get a little beyond the point at which he has already arrived. Each new fact gained by research seems but to indicate the existence of more and more important things beyond. Limit is reached and then surmounted, but soon a new limit seems to rise from the mists in the distance towards which the worker is impelled by new hopes and desires. It is this never-halting progress which distinguishes scientific from every other kind of inquiry, and particularly microscopical investigation, for it can never be completed. It deals with the illimitable. The boundaries of to-day are found to have vanished to-morrow, and the eyes and understanding begin to penetrate into regions which but a short time before had been considered far beyond the range of possible investigation.

CONDUCTIBILITY OF GLASS FOR THE GALVANIC CURRENT. —According to A. Sewarz, if two platinum wires are interposed in the same circuit, the one passing through the free air while the other lies between two glass plates, or is melted into a thick capillary tube, at a certain temperature of the tube the former glows brilliantly, while the second remains dark. If the glass becomes heated the former grows dark, whence the author concludes that the glass has become more conductive.

THE PRODUCTION OF SOUND BY RADIANT ENERGY.*

BY ALEXANDER GRAHAM BELL.

In a paper read before the American Association for the Advancement of Science, last August, I described certain experiments made by Mr. Sumner Tainter and myself which had resulted in the construction of a "*Photophone*," or apparatus for the production of sound by light; † and it will be my object to-day to describe the progress we have made in the investigation of photophonic phenomena since the date of this communication.

In my Boston paper the discovery was announced that thin disks of very many different substances *emitted sounds* when exposed to the action of a rapidly-interrupted beam of sunlight. The great variety of material used in these experiments led me to believe that sonorousness under such circumstances would be found to be a general property of all matter.

At that time we had failed to obtain audible effects from masses of the various substances which became sonorous in the condition of thin diaphragms, but this failure was explained upon the supposition that the molecular disturbance produced by the light was chiefly a surface action, and that under the circumstances of the experiments the vibration had to be transmitted through the mass of the substance in order to affect the ear. It was therefore supposed that, if we could lead to the ear air that was directly in contact with the illuminated surface, louder sounds might be obtained, and solid masses be found to be as sonorous as thin diaphragms. The first experiments made to verify this hypothesis pointed towards success. A beam of sunlight was focussed into one end of an open tube, the ear being placed at the other end. Upon interrupting the beam, a clear, musical tone was heard, the pitch of which depended upon the frequency of the interruption of the light and loudness upon the material composing the tube.

At this stage our experiments were interrupted, as circumstances called me to Europe.

While in Paris a new form of the experiment occurred to my mind, which would not only enable us to investigate the sounds produced by masses, but would also permit us to test the more general proposition that *sonorousness, under the influence of intermittent light, is a property common to all matter.*

The substance to be tested was to be placed in the interior of a transparent vessel, made of some material which (like glass) is transparent to light, but practically opaque to sound.

Under such circumstances the light could get in, but the sound produced by the vibration of the substance could not get out. The audible effects could be studied by placing the ear in communication with the interior of the vessel by means of a hearing tube.

Some preliminary experiments were made in Paris to test this idea, and the results were so promising that they were communicated to the French Academy on the 11th of October, 1880, in the note read for me by Mr. Antoine Breguet.‡ Shortly afterwards I wrote to Mr. Tainter, suggesting that he should carry on the investigation in America, as circumstances prevented me from doing so myself in Europe. As these experiments seem to have formed the common starting point for a series of independent researches of the most important character, carried on simultaneously, in America by Mr. Tainter,

and in Europe by M. Mercadier,† Prof. Tyndall,‡ W. E. Röntgen,§ and W. H. Preece,‖ I may be permitted to quote from my letter to Mr. Tainter the passage describing the experiments referred to:

METROPOLITAN HOTEL, RUE CAMBON, PARIS,
Nov. 2, 1880.

DEAR MR. TAINTER:

* * * I have devised a method of producing sounds by the action of an intermittent beam of light from substances that cannot be obtained in the shape of thin diaphragms or in the tubular form; indeed, the method is specially adapted to testing the generality of the phenomenon we have discovered, as it can be adapted to solids, liquids, and gases.

Place the substance to be experimented with in a glass test-tube, connect a rubber tube with the mouth of the test-tube, placing the other end of the pipe to the ear. Then focus the intermittent beam upon the substance in the tube. I have tried a large number of substances in this way with great success, although it is extremely difficult to get a glimpse of the sun here, and when it does shine the intensity of the light is not to be compared with that to be obtained in Washington. I got splendid effects from crystals of bichromate of potash, crystals of sulphate of copper, and from tobacco smoke. A whole cigar placed in the test-tube produced a very loud sound. I could not hear anything from plain water, but when the water was discolored with ink a feeble sound was heard. I would suggest that you might repeat these experiments and extend the results," &c., &c.

Upon my return to Washington in the early part of January,†† Mr. Tainter communicated to me the experiments he had made in my laboratory during my absence in Europe.

He had commenced by examining the sonorous properties of a vast number of substances enclosed in test-tubes in a simple empirical search for loud effects. He was thus led gradually to the discovery that cotton-wool, worsted, silk, and fibrous materials generally, produced much louder sounds than hard rigid bodies like crystals, or diaphragms such as we had hitherto used.

In order to study the effects under better circumstances he enclosed his materials in a conical cavity in a piece of brass closed by a flat plate of glass. A brass tube leading into the cavity served for connection with the hearing-tube. When this conical cavity was stuffed with worsted or other fibrous materials the sounds produced were much louder than when a test-tube was employed. This form of receiver is shown in Fig. 1.

Mr. Tainter next collected silks and worsteds of different colors, and speedily found that the darkest shades produced the best effects. Black worsted especially gave an extremely loud sound.

As white cotton-wool had proved itself equal, if not superior, to any other white fibrous material before tried, he was anxious to obtain colored specimens for comparison. Not having any at hand, however, he tried the effect of darkening some cotton-wool with lamp-black. Such a marked re-enforcement of the sound resulted that he was induced to try lamp-black alone.

About a teaspoonful of lamp-black was placed in a test-tube and exposed to an intermittent beam of sunlight. The sound produced was much louder than any heard before.

Upon smoking a piece of plate-glass, and holding it in the intermittent beam with the lamp-black surface towards the sun, the sound produced was loud enough to be heard, with attention, in any part of the room. With the lamp-black surface turned from the sun the sound was much feebler.

Mr. Tainter repeated these experiments for me immediately upon my return to Washington, so that I might verify his results.

Upon smoking the interior of the conical cavity shown in Fig. 1, and then exposing it to the intermittent beam, with the glass lid in position as shown, the effect was perfectly startling. The sound was so loud as to be actually painful to an ear placed closely against the end of the hearing-tube.

The sounds, however, were sensibly louder when we placed some smoked wire gauze in the receiver, as illustrated in the drawing, Fig. 1.*

When the beam was thrown into a resonator, the interior of which had been smoked over a lamp, most curious alternations of sound and silence were observed. The interrupting disk was set rotating at a high rate of speed, and was then allowed to come gradually to rest. An extremely feeble musical tone was at first heard, which gradually fell in pitch as the rate of interruption grew less. The loudness of the sound produced varied in the most interesting manner. Minor re-inforcements were constantly occurring, which became more and more marked as the true pitch of the resonator was neared. When at last the frequency of interruption corresponded to the frequency of the fundamental of the resonator, the sound produced was so loud that it might have been heard by an audience of hundreds of people.

The effects produced by lamp-black seemed to me to be very extraordinary, especially as I had a distinct recollection of experiments made in the Summer of 1880 with smoked diaphragms, in which no such re-enforcement was noticed.

Upon examining the records of our past photophonic experiments we found in vol. vii, p. 57, the following note:

"Experiment V.—Mica diaphragm covered with lamp-black on side exposed to light.

"Result: distinct sound about same as without lamp-black.—*A. G. B. July 18th,* 1880.

"Verified the above, but think it somewhat louder than when used without lamp-black.—*S. T., July 18th,* 1880.

Upon repeating this old experiment we arrived at the same result as that noted. Little if any augmentation of sound resulted from smoking the mica. In this experiment the effect was observed by placing the mica diaphragm against the ear and also by listening through a hearing-tube, one end of which was closed by the diaphragm. The sound was found to be more audible through the free air when the ear was placed as near to the lamp-black surface as it could be brought without shading it.

At the time of my communication to the American Association I had been unable to satisfy myself that the substances which had become sonorous under the direct influence of intermittent sunlight were capable of reproducing the sounds of articulate speech under the action of an undulatory beam from our photophonic transmitter. The difficulty in ascertaining this will be understood by considering that the sounds emitted by thin diaphragms and tubes were so feeble that it was impracticable to produce audible effects from substances in these conditions at any considerable distance away from the transmitter; but it was equally impossible to judge of the effects produced by our articulate transmitter at a short distance away because the speaker's voice was directly audible through the air. The extremely loud sounds produced from lamp-black have enabled us to demonstrate the feasibility of using this substance in an articulating photophone in place of the electrical receiver formerly employed.

The drawing (Fig. 2*) illustrates the mode in which the experiment was conducted. The diaphragm of the transmitter (A) was only 5 centimetres in diameter, the diameter of the receiver (B) was also 5 centimetres, and the distance between the two was 40 metres, or 800 times the diameter of the transmitting diaphragm. We were unable to experiment at greater distances without

a heliostat on account of the difficulty of keeping the light steadily directed on the receiver. Words and sentences spoken into the transmitter in a low tone of voice were audibly reproduced by the lamp-black receiver.

In Fig. 3* is shown a mode of interrupting a beam of sunlight for producing distant effects without the use of lenses. Two similarly-perforated disks are employed, one of which is set in rapid rotation while the other remains stationary. This form of interrupter is also admirably adapted for work with artificial light. The receiver illustrated in the drawing consists of a parabolic reflector, in the focus of which is placed a glass vessel (A) containing lamp-black or other sensitive substance, and connected with a hearing-tube. The beam of light is interrupted by its passage through the two slotted disks shown at B, and in operating the instrument musical signals like the dots and dashes of the Morse alphabet are produced from the sensitive receiver (A) by slight motions of the mirror (C) about its axis (D).

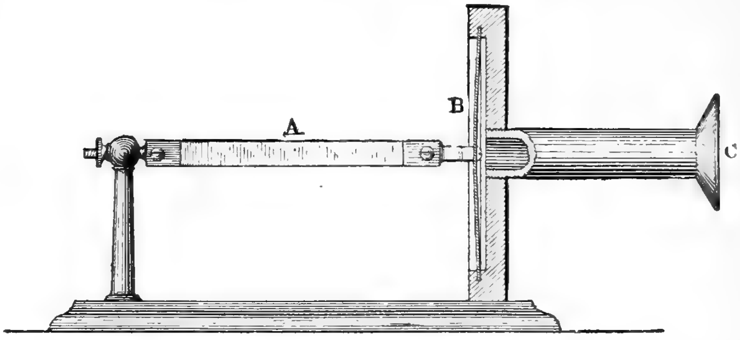

Fig. 5.

In place of the parabolic reflector shown in the figure, a conical reflector like that recommended by Prof. Sylvanus Thompson† can be used, in which case a cylindrical glass vessel would be preferable to the flask (A) shown in the figure.

In regard to the sensitive materials that can be employed, our experiments indicate that in the case of solids the physical condition and the color are two conditions that markedly influence the intensity of the sonorous effects. *The loudest sounds are produced from substances in a loose, porous, spongy condition, and from those that have the darkest or most absorbent colors.*

The materials from which the best effects have been produced are cotton-wool, worsted, fibrous materials generally, cork, sponge, platinum and other metals in a spongy condition, and lamp-black.

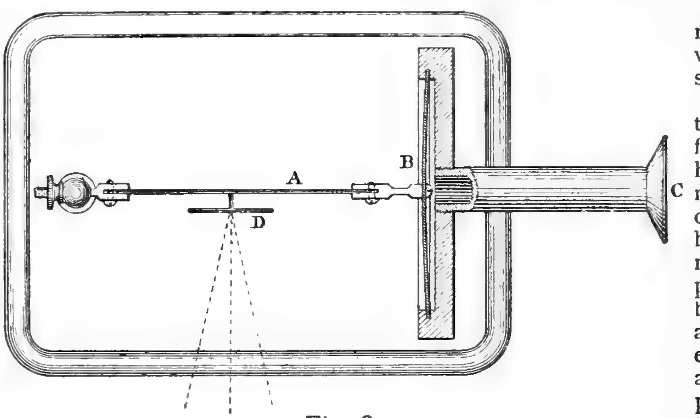

Fig. 6.

The loud sounds produced from such substances may perhaps be explained in the following manner: Let us consider, for example, the case of lamp-black—a substance which becomes heated by exposure to rays of all refrangibility. I look upon a mass of this substance as a sort of sponge, with its pores filled with air instead of water. When a beam of sunlight falls upon this mass the particles of lamp-black are heated, and consequently expand, causing a contraction of the air-spaces or pores among them.

Under these circumstances a pulse of air should be expelled, just as we would squeeze out water from a sponge.

The force with which the air is expelled must be greatly increased by the expansion of the air itself, due to contact with the heated particles of lamp-black. When the light is cut off the converse process takes place. The lamp-black particles cool and contract, thus enlarging the air spaces among them, and the enclosed air also becomes cool. Under these circumstances a partial vacuum should be formed among the particles, and the outside air would then be absorbed, as water is by a sponge when the pressure of the hand is removed.

I imagine that in some such manner as this a wave of condensation is started in the atmosphere each time a beam of sunlight falls upon lamp-black, and a wave of rarefaction is originated when the light is cut off. *We can thus understand how it is that a substance like lamp-black produces intense sonorous vibrations in the surrounding air, while at the same time it communicates a very feeble vibration to the diaphragm or solid bed upon which it rests.*

This curious fact was independently observed in England by Mr. Preece, and it led him to question whether, in our experiments with thin diaphragms, the sound heard was due to the vibration of the disk or (as Prof. Hughes had suggested) to the expansion and contraction of the air in contact with the disk confined in the cavity behind the diaphragm. In his paper read before the Royal Society on the 10th of March, Mr. Preece describes experiments from which he claims to have proved that the effects are wholly due to the vibrations of the confined air, and that the *disks do not vibrate at all.*

I shall briefly state my reasons for disagreeing with him in this conclusion:

1. When an intermittent beam of sunlight is focussed upon a sheet of hard rubber or other material, a musical tone can be heard, not only by placing the ear immediately behind the part receiving the beam, but by placing it against any portion of the sheet, even though this may be a foot or more from the place acted upon by the light.

2. When the beam is thrown upon the diaphragm of a "Blake Transmitter," a loud musical tone is produced by a telephone connected in the same galvanic circuit with the carbon button (A) Fig. 4.* Good effects are also produced when the carbon button (A) forms, with the battery (B), a portion of the primary circuit of an induction coil, the telephone (C) being placed in the secondary circuit.

In these cases the wooden box and mouth-piece of the transmitter should be removed, so that no air-cavities may be left on either side of the diaphragm.

It is evident, therefore, that in the case of thin disks a real vibration of the diaphragm is caused by the action of the intermittent beam, independently of any expansion and contraction of the air confined in the cavity behind the diaphragm.

Lord Rayleigh has shown mathematically that a to-and-fro vibration, of sufficient amplitude to produce an audible

*See page 247 for illustrations.

† Phil. Mag., April, 1881, vol. xi, p. 286.

* See page 248 for illustrations.

sound, would result from a periodical communication and abstraction of heat, and he says: "We may conclude, I think, that there is, at present no reason for discarding the obvious explanation that the sounds in question are due to the bending of the plates under unequal heating." (Nature, xxiii, p. 274). Mr. Preece, however, seeks to prove that the sonorous effects cannot be explained upon this supposition; but his experimental proof is inadequate to support his conclusion. Mr. Preece expected that if Lord Rayleigh's explanation was correct, the expansion and contraction of a thin strip under the influence of an intermittent beam could be caused to open and close a galvanic circuit so as to produce a musical tone from a telephone in the circuit. But this was an inadequate way to test the point at issue, for Lord Rayleigh has shown (Proc. of Roy. Soc., 1877) that an audible sound can be produced by a vibration whose amplitude is *less than a ten-millionth of a centimetre*, and certainly such a vibration as that would not have sufficed to operate a "make-and-break contact" like that used by Mr. Preece. The negative results obtained by him cannot, therefore, be considered conclusive.

The following experiments (devised by Mr. Tainter) have given results decidedly more favorable to the theory of Lord Rayleigh than to that of Mr. Preece:

1. A strip (A), similar to that used in Mr. Preece's experiment was attached firmly to the centre of an iron diaphragm (B) as shown in Fig. 5, and was then pulled taut at right angles to the plane of the diaphragm. When the intermittent beam was focussed upon the strip (A), a clear musical tone could be heard by applying the ear to the hearing tube (C).

This seemed to indicate a rapid expansion and contraction of the substance under trial.

But a vibration of the diaphragm (B) would also have resulted if the thin strip (A) had acquired a to-and-fro motion, due either to the direct impact of the beam or to the expansion of the air in contact with the strip.

2. To test whether this had been the case an additional strip (D) was attached by its central point only to the strip under trial, and was then submitted to the action of the beam, as shown in Fig. 6.

It was presumed that if the vibration of the diaphragm (B) had been due to a *pushing force* acting on the strip (A), that the addition of the strip (D) would not interfere with the effect. But if, on the other hand, it had been due to the longitudinal expansion and contraction of the strip (A), the sound would cease, or at least be reduced. The beam of light falling upon the strip (D) was now interrupted as before by the rapid rotation of a perforated disk, which was allowed to come gradually to rest.

No sound was heard excepting at a certain speed of rotation, when a feeble musical tone became audible.

This result is confirmatory of the first.

The audibility of the effect at a particular rate of interruption suggests the explanation that the strip (D) had a normal rate of vibration of its own.

When the frequency of the interruption of the light corresponded to this, the strip was probably thrown into vibration after the manner of a tuning fork, in which case a to-and-fro vibration would be propagated down its stem or central support to the strip (A).

This indirectly proves the value of the experiment.

The list of solid substances that have been submitted to experiment in my laboratory is too long to be quoted here, and I shall merely say that we have not yet found one solid body that has failed to become sonorous under proper conditions of experiment.*

* Carbon and thin microscope glass are mentioned in my Boston paper as non-responsive, and powdered chlorate of potash in the communication to the French Academy, (Comptes Rendus, vol. xlc, p. 595.) All these substances have since yielded sounds under more careful conditions of experiment.

EXPERIMENTS WITH LIQUIDS.

The sounds produced by liquids are much more difficult to observe than those produced by solids. The high absorptive power possessed by most liquids would lead one to expect intense vibrations from the action of intermittent light, but the number of sonorous liquids that have so far been found is extremely limited, and the sounds produced are so feeble as to be heard only by the greatest attention and under the best circumstances of experiment. In the experiments made in my laboratory a very long test-tube was filled with the liquid under examination, and a flexible rubber-tube was slipped over the mouth far enough down to prevent the possibility of any light reaching the vapor above the surface. Precautions were also taken to prevent reflection from the bottom of the test-tube. An intermittent beam of sunlight was then focussed upon the liquid in the middle portion of the test-tube by means of a lens of large diameter.

RESULTS.

Clear water	No sound audible.
Water discolored by ink	Feeble sound.
Mercury	No sound heard.
Sulphuric ether*	Feeble, but distinct sound.
Ammonia	" " " "
Ammonio-sulphate of copper.	" " " "
Writing ink	" " " "
Indigo in sulphuric acid	" " " "
Chloride of copper*	" " " "

The liquids distinguished by an asterisk gave the best sounds.

Acoustic vibrations are always much enfeebled in passing from liquids to gases, and it is probable that a form of experiment may be devised which will yield better results by communicating the vibrations of the liquid to the ear through the medium of a solid rod.

EXPERIMENTS WITH GASEOUS MATTER.

On the 29th of November, 1880, I had the pleasure of showing to Prof. Tyndall in the laboratory of the Royal Institution the experiments described in the letter to Mr. Tainter from which I have quoted above, and Prof. Tyndall at once expressed the opinion that the sounds were due to rapid changes of temperature in the body submitted to the action of the beam. Finding that no experiments had been made at that time to test the sonorous properties of different gases, he suggested filling one test-tube with the vapor of sulphuric ether, (a good absorbent of heat,) and another with the vapor of bisulphide of carbon, (a poor absorbent,)and he predicted that if any sound was heard it would be louder in the former case than in the latter.

The experiment was immediately made, and the result verified the prediction.

Since the publication of the memoirs of Röntgen* and Tyndall† we have repeated these experiments, and have extended the inquiry to a number of other gaseous bodies, obtaining in every case similar results to those noted in the memoirs referred to.

The vapors of the following substances were found to be highly sonorous in the intermittent beam: Water vapor, coal gas, sulphuric ether, alcohol, ammonia, amylene, ethyl bromide, diethylamene, mercury, iodine, and peroxide of nitrogen. The loudest sounds were obtained from iodine and peroxide of nitrogen.

I have now shown that sounds are produced by the direct action of intermittent sunlight from substances in every physical condition (solid, liquid, and gaseous), and the probability is, therefore, very greatly increased that sonorousness, under such circumstances, will be found to be a universal property of matter.

*Ann. der Phys. und Chem., 1881, No. 1, p. 155.

†Proc. Roy. Soc., vol. xxxi, p. 307.

UPON SUBSTITUTES FOR SELENIUM IN ELECTRICAL RECEIVERS.

At the time of my communication to the American Association the loudest effects obtained were produced by the use of selenium, arranged in a cell of suitable construction, and placed in a galvanic circuit with a telephone. Upon allowing an intermittent beam of sunlight to fall upon the selenium a musical tone of great intensity was produced from the telephone connected with it.

But the selenium was very inconstant in its action. It was rarely, if ever, found to be the case, that two pieces of selenium (even of the same stick) yielded the same results under identical circumstances of annealing, etc. While in Europe last autumn, Dr. Chichester Bell, of University College, London, suggested to me that this inconstancy of result might be due to chemical impurities in the selenium used. Dr. Bell has since visited my laboratory in Washington, and has made a chemical examination of the various samples of selenium I had collected from different parts of the world. As I understand it to be his intention to publish the results of this analysis very soon, I shall make no further mention of his investigation than to state that he has found sulphur, iron, lead, and arsenic in the so-called "selenium," with traces of organic matter; that a quantitative examination has revealed the fact that sulphur constitutes nearly one per cent. of the whole mass; and that when these impurities are eliminated the selenium appears to be more constant in its action and more sensitive to light.

Prof. W. G. Adams* has shown that tellurium, like selenium, has its electrical resistance affected by light, and we have attempted to utilize this substance in place of

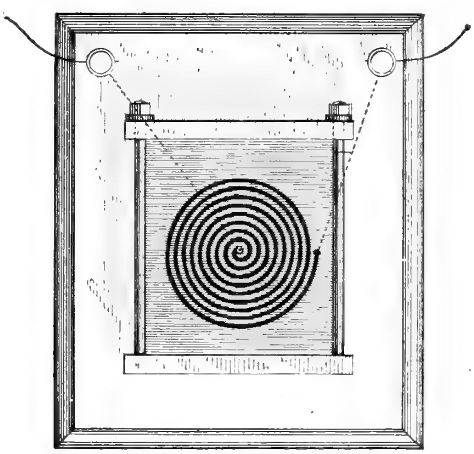

Fig. 7.

selenium. The arrangement of cell (shown in Fig. 7) was constructed for this purpose in the early part of 1880; but we failed at that time to obtain any indications of sensitiveness with a reflecting galvanometer. We have since found, however, that when this tellurium spiral is connected in circuit with a galvanic battery and telephone, and exposed to the action of an intermittent beam of sunlight, a distinct musical tone is produced by the telephone. The audible effectis much increased by placing the tellurium cell with the battery in the primary circuit of an induction coil, and placing the telephone in the secondary circuit.

The enormously high resistance of selenium and the extremely low resistance of tellurium suggested the thought that an alloy of these two substances might possess intermediate electrical properties. We have accordingly mixed together selenium and tellurium in different proportions, and while we do not feel warranted at the present time in making definite statements concerning the results, I may say that such alloys have proved to be sensitive to the action of light.

*Proc. Roy. Soc., vol. xxiv, p. 163.

It occurred to Mr. Tainter before my return to Washington last January that the very great molecular disturbance produced in lamp-black by the action of intermittent sunlight should produce a corresponding disturbance in an electric current passed through it, in which case lamp-black could be employed in place of selenium in an electrical receiver. This has turned out to be the case, and the importance of the discovery is very great, especially when we consider the expense of such rare substances as selenium and tellurium.

The form of lamp-black cell we have found most effec-

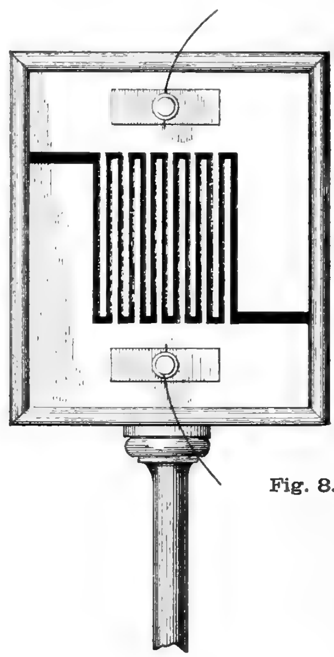

Fig. 8.

tive is shown in Fig. 8. Silver is deposited upon a plate of glass, and a zigzag line is then scratched through the film, as shown, dividing the silver surface into two portions insulated from one another, having the form of two combs with interlocking teeth.

Each comb is attached to a screw-cup, so that the cell can be placed in an electrical circuit when required. The surface is then smoked until a good film of lamp-black is obtained, filling the interstices between the teeth of the silver combs. When the lamp-black cell is connected with a telephone and galvanic battery, and exposed to the influence of an intermittent beam of sunlight, a loud musical tone is produced by the telephone. This result seems to be due rather to the physical condition than to the nature of the conducting material employed, as metals in a spongy condition produce similar effects. For instance, when an electrical current is passed through spongy platinum while it is exposed to intermittent sunlight, a distinct musical tone is produced by a telephone in the same circuit. In all such cases the effect is increased by the use of an induction coil; and the sensitive cells can be employed for the reproduction of articulate speech as well as for the production of musical sounds.

We have also found that loud sounds are produced from lamp-black by passing through it an intermittent electrical current; and that it can be used as a telephonic receiver for the reproduction of articulate speech by electrical means.

A convenient mode of arranging a lamp-black cell for

experimental purposes is shown in Fig. 9. When an intermittent current is passed through the lamp-black, (A) or when an intermittent beam of sunlight falls upon it through the glass plate (B) a loud musical tone can be heard by applying the ear to the hearing-tube (C). When the light and the electrical current act simultaneously, two musical tones are perceived, which produce beats when nearly of the same pitch. By proper arrangements a complete interference of sound can undoubtedly be produced.

UPON THE MEASUREMENT OF THE SONOROUS EFFECTS PRODUCED BY DIFFERENT SUBSTANCES.

We have observed that different substances produce sounds of very different intensities under similar circumstances of experiment, and it has appeared to us that very valuable information might be obtained if we could measure the audible effects produced. For this purpose we have constructed several different forms of apparatus for studying the effects, but as our researches are not yet complete, I shall confine myself to a simple description of some of the forms of apparatus we have devised.

When a beam of light is brought to a focus by means of a lens, the beam diverging from the focal point becomes weaker as the distance increases in a calculable degree. Hence, if we can determine the distances from the focal point at which two different substances emit sounds of equal intensity, we can calculate their relative sonorous powers.

Preliminary experiments were made by Mr. Tainter during my absence in Europe to ascertain the distance from the focal point of a lens at which the sound produced by a substance became inaudible. A few of the results obtained will show the enormous differences existing between different substances in this respect.

Mr. Tainter was convinced from these experiments that this field of research promised valuable results, and he at once devised an apparatus for studying the effects, which he described to me upon my return from Europe. The apparatus has since been constructed and I take great pleasure in showing it to you to-day.

(1.) A beam of light is received by two similar lenses (A B, Fig. 10*), which bring the light to a focus on either side of the interrupting disk (C). The two substances, whose sonorous powers are to be compared, are placed in the receiving vessels (D E)—so arranged as to expose equal surfaces to the action of the beam—which communicate by flexible tubes (F G) of equal length, with the common hearing-tube (H). The receivers (D E) are placed upon slides, which can be moved along the graduated supports (I K). The beams of light passing through the interrupting disk (C), are alternately cut off by the swinging of a pendulum (L). Thus a musical tone is produced alternately from the substance in D and from that in E. One of the receivers is kept at a constant point upon its scale, and the other receiver is moved towards or from the focus of its beam until the ear decides that the sounds produced from D and E are of equal intensity. The relative positions of the receivers are then noted.

(2.) Another method of investigation is based upon the production of an interference of sound, and the apparatus employed is shown in Fig. 11.* The interrupter consists of a tuning-fork (A), which is kept in continuous vibration by means of an electro-magnet (B).

A powerful beam of light is brought to a focus between the prongs of the tuning-fork (A), and the passage of the beam is more or less obstructed by the vibration the opaque screens (C D) carried by the prongs of the fork.

As the tuning-fork (A) produces a sound by its own vibration, it is placed at a sufficient distance away to be inaudible through the air, and a system of lenses is employed for the purpose of bringing the undulating beam of light to the receiving lens (E) with as little loss as possible. The two receivers (F G) are attached to slides (H I) which move upon opposite sides of the axis of the beam, and the receivers are connected by flexible tubes of unequal length (K L) communicating with the common hearing-tube (M).

The length of the tube (K) is such that the sonorous vibrations from the receivers (F G) reach the common hearing-tube (M) in opposite phases. Under these circumstances silence is produced when the vibrations in the receivers (F G) are of equal intensity. When the intensities are unequal, a residual effect is perceived. In operating the instrument the position of the receiver (G) remains constant, and the receiver (F) is moved to or from the focus of the beam until complete silence is produced. The relative positions of the two receivers are then noted.

(3). Another mode is as follows: The loudness of a musical tone produced by the action of light is compared with the loudness of a tone of similar pitch produced by electrical means. A rheostat introduced into the circuit enables us to measure the amount of resistance required to render the electrical sound equal in intensity to the other.

* See pages 248 and 249 for illustrations.

(4.) If the tuning-fork (A) in Fig. 11 is thrown into vibration by an undulatory instead of an intermittent current passed through the electro-magnet (B), it is probable that a musical tone, electrically produced in the receiver (F) by the action of the same current, would be found capable of extinguishing the effect produced in the receiver (G) by the action of the undulatory beam of light, in which case it should be possible to establish an acoustic balance between the effects produced by light and electricity by introducing sufficient resistance into the electric circuit.

UPON THE NATURE OF THE RAYS THAT PRODUCE SONOROUS EFFECTS IN DIFFERENT SUBSTANCES.

In my paper read before the American Association last August and in the present paper I have used the word "light" in its usual rather than its scientific sense, and I have not hitherto attempted to discriminate the effects produced by the different constituents of ordinary light, the thermal, luminous, and actinic rays. I find, however, that the adoption of the word "photophone" by Mr. Tainter and myself has led to the assumption that we believed the audible effects discovered by us to be due entirely to the action of luminous rays. The meaning we have uniformly attached to the words "photophone" and "light" will be obvious from the following passage, quoted by my Boston paper:

"Although effects are produced as above shown by forms of radiant energy, which are invisible, we have named the apparatus for the production and reproduction of sound in this way the 'photophone' *because an ordinary beam of light contains the rays which are operative.*"

To avoid in future any misunderstandings upon this point we have decided to adopt the term "*radiophone*," proposed by M. Mercadier, as a general term signifying an apparatus for the production of sound by any form of radiant energy, limiting the words *thermophone, photophone*, and *actinophone*, to apparatus for the production of sound by thermal, luminous, or actinic rays respectively.

M. Mercadier, in the course of his researches in radiophony, passed an intermittent beam from an electric lamp through a prism, and then examined the audible effects produced in different parts of the spectrum. (*Comptes Rendus*, Dec. 6th, 1880.)

We have repeated this experiment, using the sun as our source of radiation, and have obtained results somewhat different from those noted by M. Mercadier.

A beam of sunlight was reflected from a heliostat (A, Fig. 12*) through an achromatic lens, (B) so as to form an image of the sun upon the slit (C).

The beam then passed through another achromatic lens (D) and through a bisulphide of carbon prism (E), forming a spectrum of great intensity, which, when focussed upon a screen, was found to be sufficiently pure to show the principal absorption lines of the solar spectrum.

The disk-interrupter (F) was then turned with sufficient rapidity to produce from five to six hundred interruptions of the light per second, and the spectrum was explored with the receiver (G), which was so arranged that the lamp-black surface exposed was limited by a slit, as shown.

Under these circumstances sounds were obtained in every part of the visible spectrum, excepting the extreme half of the violet, as well as in the ultra-red. A continuous increase in the loudness of the sound was observed upon moving the receiver (G) gradually from the violet into the ultra-red. The point of maximum sound lay very far out in the ultra-red. Beyond this point the sound began to decrease, and then stopped so suddenly that a very slight motion of the receiver (G) made all the difference between almost maximum sound and complete silence.

*See page 249 for illustrations.

(2.) The lamp-blacked wire gauze was then removed and the interior of the receiver (G) was filled with red-worsted. Upon exploring the spectrum as before, entirely different results were obtained. The maximum effect was produced in the green at that part where the red worsted appeared to be black. On either side of this point the sound gradually died away, becoming inaudible on the one side in the middle of the indigo, and on the other at a short distance outside the edge of the red.

(3.) Upon substituting green silk for red worsted the limits of audition appeared to be the middle of the blue and a point a short distance out in the ultra-red. Maximum in the red.

(4.) Some hard-rubber shavings were now placed in the receiver (G). The limits of audibility appeared to be on the one hand the junction of the green and blue, and on the other the outside edge of the red. Maximum in the yellow. Mr. Tainter thought he could hear a little way into the ultra-red, and to his ear the maximum was about the junction of the red and orange.

(5.) A test-tube containing the vapor of sulphuric ether was then substituted for the receiver (G). Commencing at the violet end, the test-tube was gradually moved down the spectrum and out into the ultra-red without audible effect, but when a certain point far out in the ultra-red was reached a distinct musical tone suddenly made its appearance, which disappeared as suddenly on moving the test-tube a very little further on.

(6.) Upon exploring the spectrum with a test-tube containing the vapor of iodine the limits of audibility appeared to be the middle of the red and the junction of the blue and indigo. Maximum in the green.

(7.) A test-tube containing peroxide of nitrogen was substituted for that containing iodine. Distinct sounds were obtained in all parts of the visible spectrum, but no sounds were observed in the ultra-red.

The maximum effect seemed to me to be in the blue. The sounds were well marked in all parts of the violet, and I even fancied that the audible effect extended a little way into the ultra-violet, but of this I cannot be certain. Upon examining the absorption spectrum of peroxide of nitrogen it was at once observed that the maximum sound was produced in that part of the spectrum where the greatest number of absorption lines made their appearance.

(8.) The spectrum was now explored by a selenium cell, and the audible effects were observed by means of a telephone in the same galvanic circuit with the cell. The maximum effect was produced in the red. The audible effect extended a little way into the ultra-red on the one hand and up as high as the middle of the violet on the other.

Although the experiments so far made can only be considered as preliminary to others of a more refined nature, I think we are warranted in concluding that *the nature of the rays that produce sonorous effects in different substances depends upon the nature of the substances that are exposed to the beam, and that the sounds are in every case due to those rays of the spectrum that are absorbed by the body.*

THE SPECTROPHONE.

Our experiments upon the range of audibility of different substances in the spectrum have led us to the construction of a new instrument for use in spectrum analysis, which was described and exhibited to the Philosophical Society of Washington last Saturday.* The eye-piece of a spectroscope is removed, and sensitive substances are placed in the focal point of the instrument behind an opaque diaphragm containing a slit. These substances are put in communication with the ear by means of a hearing tube, and thus the instrument is converted into a veritable "spectrophone" like that shown in Fig. 13.†

* Proc. of Phil. Soc. of Washington, April 16, 1881.

†See page 250 for illustrations.

Suppose we smoke the interior of our spectrophonic receiver, and fill the cavity with peroxide of nitrogen gas. We have then a combination that gives us good sounds in all parts of the spectrum (visible and invisible), except the ultra-violet. Now, pass a rapidly-interrupted beam of light through some substance whose absorption spectrum is to be investigated, and bands of sound and silence are observed upon exploring the spectrum, the silent positions corresponding to the absorption bands. Of course, the ear cannot for one moment compete with the eye in the examination of the visible part of the spectrum; but in the invisible part beyond the red, where the eye is useless, the ear is invaluable. In working in this region of the spectrum, lamp-black alone may be used in the spectrophonic receiver. Indeed, the sounds produced by this substance in the ultra-red are so well marked as to constitute our instrument a most reliable and convenient substitute for the thermo-pile. A few experiments that have been made may be interesting.

(1.) The interrupted beam was filtered through a saturated solution of alum.

Result: The range of audibility in the ultra-red was slightly reduced by the absorption of a narrow band of the rays of lowest refrangibility. The sounds in the visible part of the spectrum seemed to be unaffected.

(2.) A thin sheet of hard rubber was interposed in the path of the beam.

Result: Well-marked sounds in every part of the ultra-red. No sounds in the visible part of the spectrum, excepting the extreme half of the red.

These experiments reveal the cause of the curious fact alluded to in my paper read before the American Association last August—that sounds were heard from selenium when the beam was filtered through both hard rubber and alum at the same time. (See table of results in Fig. 14.*)

(3.) A solution of ammonio-sulphate of copper was tried.

Result: When placed in the path of the beam the spectrum disappeared, with the exception of the blue and violet end. To the eye the spectrum was thus reduced to a single broad band of blue-violet light. To the ear, however, the spectrum revealed itself as two bands of sound with a broad space of silence between. The invisible rays transmitted constituted a narrow band just outside the red.

I think I have said enough to convince you of the value of this new method of examination, but I do not wish you to understand that we look upon our results as by any means complete. It is often more interesting to observe the first totterings of a child than to watch the firm tread of a full-grown man, and I feel that *our* first footsteps in this new field of science may have more of interest to you than the fuller results of mature research. This must be my excuse for having dwelt so long upon the details of incomplete experiments.

I recognize the fact that the spectrophone must ever remain a mere adjunct to the spectroscope, but I anticipate that it has a wide and independent field of usefulness in the investigation of absorption spectra in the ultra-red.

CONTRIBUTIONS TO COMPARATIVE PSYCHOLOGY.

By S. V. Clevenger, M. D.

I. INSTINCT AND REASON.

In St. George Mivart's recent work, "The Cat," Chap. XI treats of the Psychology of that animal. Amidst the usual ambiguity to be found wherever such subjects are treated, Mivart occasionally formulates his views. On page 369 his words admit of no other interpretation than an acknowledgement that instinct is nearly, though not quite pure automatism. The possession of reason by the cat is at first evasively dealt with, and finally on page 373, flatly denied. Mivart finds fault with Herbert Spencer's views as to instinct: "According to Mr. Spencer it is a higher development of reason which it has replaced, owing to the establishment of a more perfect adjustment of inner relations to outer relations than exists where mere reason is concerned." That opinion of Spencer's is one of the many which deserves to be rescued from the oblivion his involved style threatens to inflict upon the mass of his writings. From pure morphological and histological observations I have been led to the conclusions at which Spencer arrives by a wholly different route. The nervous system is a net-work of conducting substance interrelating the units of the animal body.

In an article by Spitzka ("Insane Delusions" page 34, *Journal Nervous and Mental Disease*, January, 1881), occur the following words: "In fact I should, if asked to point to the chief factor on which the higher powers of the human brain depend, lay less stress on the cortical development as such, than in the immense preponderance of the white substance due to the massive associating tracts."

Automaticity created by unvarying persistence of impressions resulting in certain definite movements, whether occurring through heredity, or during the lifetime of the individual (as proficiency in piano playing, etc.), has, for its material substratum, absolute definiteness of association of those parts which the nervous system connects; thus, regarded as a colony, the component individuals of the organism are brought into thorough automatic relationship with one another, and to that part of the environment to which the organism responds instinctively.

On the other hand reason is represented by the disconnected, shifting, short and long nerve fibres, as the arcuate of the cerebrum, not as yet assigned to any definite location. Reason thus is the struggle toward automatism. Instinct is the outcome of the struggle. Broadly viewing the higher nervous organization of animals there is a perpetual tendency to the establishment of nerve routes which would eventuate in handing over perfect control of every function to the highest nerve system. Spitzka expresses this (Architecture of the Brain, page 649 J. N. & M. D. Oct. 1879): "With the development of these highest projection fibres, the cerebral hemispheres gradually encroached on the independency of the lower ganglia, until in its maximal development as found in man, it resembles a great empire which holds a number of tributary states in sway under a common powerful rule. The automatical unity now attained, finds its parallel psychical culmination in that more perfect consciousness of the *ego*, which is peculiar to man." There is nothing debatable about this tendency on the part of the nervous system; the greater relative masses of the longitudinal and transverse associating tracts in the spinal cords, spinal and cerebro-spinal nerves and brains of all animals, in proportion to their reasoning and instinctive abilities, point to a prevailing law which seeks the reduction of all animal movements to the simplest mechanical methods. A corollary from instinct being perfected reason, would be that the salvation of reason to the race depended upon the vicissitudes and shifting circumstances with which we are surrounded, amounting to rescue from the fate mentioned by Wallace in degradation through parasitism. DeQuincey calls the human brain a palimpsest. In old age new tissues of any kind are formed with difficulty, new routes in the brain strive in vain for establishment; in senility the nervous tracts established in youth, and upon which all subsequent associations are founded, are the last to suffer disintegration, hence youthful recollections become at this time more vivid.

*See page 250 for illustrations.

FURTHER NOTES ON THE BRAIN OF THE SAUROPSIDA.

By E. C. Spitzka, M. D.

1. A most notable feature of the cerebral hemispheres of such reptiles as the Alligator, Iguana and sea-turtle is the absence of a proper choroid plexus in the lateral ventricle. This is the more remarkable as in the amphibia, the choriod plexus is very well developed. The sea-turtle has a few vascular coils protruding into the lateral ventricle at its posterior portion; nothing of the kind can be identified in the Iguana or in birds.

2. On removing the inner cerebral wall of an Alligator's hemisphere it can be seen that the Corpus Striatum is continued into the pedicle of the olfactory bulb, as a distinct prominence. In fact the substance of the pedicle is in the main a continuation of the Corpus Striatum and of the basilar part of the hemisphere, the dorso-lateral cortex becoming attenuated to a mere film on entering that structure. The lumen of the pedicle is a continuation of that recess of the lateral ventricle which undermines the mesal side of the root of the Corpus Striatum.

3. The Corpus Striatum is relatively more massive in the Sauropsida, than in any other animal group. It reaches its maximum in birds, where also the lateral ventricle is most reduced. It seems as if a secondary fusion must occur, as explaining the apparent obliteration noted in the latter group.

4. A careful study of the structure designated as the anterior commissure of the reptile's brain has failed to convince me that this structure is to be considered as the homologue of the same commissure in the mammalian brain. So far I am inclined to consider it as representing the Corpus Callosum, at least in part. Its fibres are medullated.

5. The inner face of the hemispheric wall is finely striated; this is due to the fasciculation of the nerve fibres lying subjacent to the ventricle; they correspond to the Corona radiata.

6. It is not difficult to see that the greater part of the cerebral surface, that is, the entire basilar and more than half of its lateral aspect is the representative of what in the mammalia is the least voluminous and functionally the least important portion, namely of the Island of Reil and the præperforate region. In some reptiles (Chelydra, Boa) these two districts or their homologues are demarcated from each other by a shallow sulcus. The area homologous with the Island of Reil, corresponds pretty accurately to the base of the Corpus Striatum; the other, represented in mammals by the *Substantia perforata anterior* is a bodily continuation of the thalamic halves, a marked constriction separates them from the thalami proper, on the dorsal surface. Perhaps they constitute a species of prothalamus.

There remains then as the representative of the convoluted portion of the cerebral hemispheres of the placental mammalia, merely the delicate thin walled portion of the reptilian cerebrum. It is here where the pyramidal nerve cells are found in the best development. In the tenuity of the subjacent nerve layer, it closely resembles the hemispheric wall of the mammalian embryo.

7. There are two varieties of cerebelli found in the Sauropsida; to these might be added a third or fundamental type from which the other or divergent types may be derived.

The fundamental type is found in serpents and apodal lacertians, as well as in Chelonia of a low type (Boa, Bascanion, Pseudopus, Chelydra). Here the cerebellum is a mere lip covering the entrance to the mesencephalic ventricle, as in the Amphibia, and in embryos.

The second type is found in the higher Chelonia (Cistudo, Naunemys, Calemys, Thalassochelys) and the Crocodilia (Alligator). Here the lip has become inflated, and extends like a hollow hood directly backwards over the fourth ventricle. It corresponds in its best development to nothing so much as to a baseball cap. This resemblance is heightened by the presence in the Alligator and Thallassochelys of a distant rim. I have found, in an individual of Cistudo, the Cerebellar cap dented from above, and turned inside out, as it were; the individual had suffered prolonged starvation.

The third variety is found in lacertians (Iguana) and birds (Struthio, Aro, Trichoglossus, Gallus, Columba, Phœnicopterus, etc). Here the cerebellar lip creeps up, as it were, on the posterior declivity of the optic (and post optic) lobes, firmly tied down to these by the arachnoid. In birds the lip becomes reflected from the highest point, and descends backwards.

The highest form of the second variety is found in the Alligator, where in the adult and in larger specimens, though not in the one or two-year-olds, there are distinct transverse sulci. In the sea-turtle an indication of transverse sulci is observed in hardened specimens; they may be artifacts, however.

8. An important feature of the reptilian brain are the lateral eminences of the Oblongata, which, from their connection with the eighth pair of cranial nerves, merit the designation of *eminentiæ acusticæ*. A reliquary fragment in the mammalia constitutes the Fasciola cinerea. But the greater portion of this, in reptiles (Alligator, Iguana) exceedingly complicated body seems to be a sort of herald of a higher cerebellar development, and the very similar lateral bodies of the human embryonic Oblongata appear to be swallowed up in the cerebellar mass. Future research must determine whether the *nuclei dentati* are derivable from these masses or whether some of the lesser cerebellar lobules monopolize them. In the Alligator they closely simulate cerebellar *folia*, and consist of gray and white substance. It is from them that arises the *eminentia transversa ventriculi quarti* so well developed in the Iguana and Alligator. In the latter the acoustic convolvuli are in morphological connection with the lateral kink of the cerebellum.

9. On comparing a series of animals beginning with the Amphibia, passing thence to the Sauropsida and ending with the mammalia, we find that there is this close correspondence to a series of mammalian embryonic and fœtal brains, that while in the lowest types the nerve fibres of the spinal cord are well provided with *myelin*, and the Oblongata presents the same maturity of structure, that it is only in higher types that the Cerebellum and Mesencephalon show the same or an approximate histological advance, which involves the Thalamus and Cerebrum in their entity only in the very highest types. This is an important confirmation of the laws laid down by Flechsig and Meynert.

ASTRONOMY.

The Morrison Observatory.

The Morrison Observatory—the gift of Miss Morrison, a former resident of Glasgow—was built at Glasgow, Missouri, in 1875. The building is well adapted to the purpose it is intended to serve, and was constructed under the supervision of Prof. C. W. Pritchett, who consulted several of the leading astronomers of the country in preparing his plans.

The position of the observatory is, latitude, 39° 16′ 16.8″ north. Longitude $1^h\ 3^m\ 5.93^s$ west of Washington. The latitude was obtained from observations recently made with the Transit Circle, and discussed by Prof. H.S. Pritchett; the longitude from an exchange of signals made with the United States Naval Observatory in 1880.

For instrumental equipment, the Morrison Observatory possesses one of Clark's finest 12¼ equatorials. It is of 17 feet focal length, and has already been the means of discovering a number of faint double stars. In 1877 and again in 1879, a large number of observations of the satellites of Mars were obtained. *Mimas* has been ob-

served on at least three occasions, and has been suspected, without being positively identified, a much larger number of times.

The Transit Circle was made by Troughton and Simms, London, in 1876 and was mounted in 1877. The construction of the instrument and the method of mounting are quite similar to the instruments in use at Greenwich, and Harvard College Observaory.

The telescope has a clear aperture of 6 inches, and a focal length of 6 feet 4 inches. The axis is cast in a single piece, into which fit the steel pivots, 3.50 inches in diameter. The Y's are of gun metal, and their bearing surfaces 2.50 inches long, 0.74 inches wide. The piers are of iron, and are firmly bolted to heavy stone caps which rest upon brick foundations. The circles are 24 inches in diameter, divided to 5′, and read by four microscopes each.

The reticule in the focus of the telescope carries 15 vertical and 5 horizontal threads—the vertical threads being all carried by the Right Ascension micrometer screw, and the horizontal threads by the declination screw. There are no fixed threads in the field.

The Transit Circle is furnished with two collimators having object glasses of 4 ft. 3 in. focal length and 4.33 in. aperture. The distance between the bearing points of the collimator Y's is 3 ft. 10 in. In the focus of each collimator are fixed two close vertical threads (about 5.3″ apart) and one horizontal thread. In the ordinary time observations it is customary to observe for collimation immediately before the observations of star transits, and then set the micrometer so as to destroy the error in collimation.

The Standard Sidereal Clock of the Observatory is Frodsham No. 1369. It was mounted in 1877, and has been running for two years past on a very small and constant rate.

In addition to these instruments, the Observatory is furnished with an excellent 4-in. Clark Comet Seeker, an Altazimuth by Gasella, and the usual barometers, thermometers, etc.

The work now being carried on is chiefly equatorial, and may be divided into two parts, as follows:

1. Double Star Work. A list consisting chiefly of binaries which have been neglected for some years (some of them for ten or twenty, or even thirty years) and will well repay observation. Besides these, a selected list of Burnham's stars, which are suspected of binarity, or which are quite new and have not been observed. Most of these stars are in the southern sky, and including the list for personal equation, will make a total of about 500 doubles. This work is well under way and will probably be concluded within a year.

2. The second part of the equatorial work consists of observations, descriptive and micrometric, upon planets and their satellites, and includes a series of observations extending over several years, upon the satellites of Saturn, and observations upon the red spot of Jupiter since its discovery at Glasgow in 1878.

With the Meridian Circle, no work is done beyond the ordinary observations for time.

The Time-Service of the Observatory, inaugurated within the past year by Prof. H. S. Pritchett, has met with well deserved success, and its value is fully appreciated by the people of the State. Two time balls are dropped by the Observatory clock—one in St. Louis and one in Kansas City—and the clock signals are regularly distributed over a large and constantly increasing area. Owing to its position—almost exactly one hour west of Washington—the Morrison Observatory will doubtless be largely depended upon in regulating the time of the Mississippi Valley, if any of the schemes for "Uniform Time" which have recently been proposed are ever adopted.

Though so well equipped instrumentally, Morrison Observatory, like many a similar institution of longer standing, is sadly crippled for want of funds: its income being barely sufficient for the support of a director without assistance. It is greatly to be regretted that one of the most promising observatories in the country should be thus curtailed in its usefulness, merely for want of proper financial support. W. C. W.

DISCOVERY OF AN ASTEROID.

The Smithsonian Institution has received from M. Foerster, of Berlin, the announcement of the discovery by M. Palisa, at Pola, on the 20th of May, 1881, of a planetoid of the thirteenth magnitude, in

R. A.	15h	3m
Dec.	—23°	2′

with a daily motion of 8m *north.*

CORRESPONDENCE.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.*]

LOCUSTS AND SUN SPOTS.

To the Editor of "SCIENCE:"

SIR: It may concern some of your readers to know that I have just made the interesting discovery, that the multiplication and migration of the Rocky Mountain Locust (*Caloptenus spretus*), has been hitherto in exact agreement with the minima of Wolf's sun spot cycles as given (Mem. As. Soc. vols. XLII and XLIII), and its decrease has as nearly accorded with the maxima, there not being a year's difference. On European areas, it may be remarked, insect migration but *rarely agrees* with these maxima and minima, the chief periods being obtainable by counting the elevens since 1846. There likewise exists this marked difference, in that while the American locust spreads to the east and west of south, European migrants come north and east.

It would be important to determine the multiplication of the Corn Weevils in relation to the sun spots. Cannot the trade keep diaries? As the more destructive kind comes from the tropic, the minimum period should be dreaded. A. H. SWINTON.

GUILDFORD, ENG., *May*, 1881.

THE VIEWS OF DR. HOLMES UPON THE PROPOSED REVISION MODIFICATIONS OF ANATOMICAL NOMENCLATURE.

We are permitted to publish the following letter from Oliver Wendell Holmes to Professor B. G. Wilder respecting the articles on "Anatomical Nomenclature" which appeared in Nos. 38 and 39 of this journal. It may not be generally known to our readers that "The Autocrat of the Breakfast-table" has been for many years the Professor of Anatomy in the Harvard Medical School. BOSTON, May 3, 1881.

Dear Dr. Wilder:

I have read carefully your papers on Nomenclature. I entirely approve of it as an *attempt*, an attempt which I hope will be partially successful, for no such sweeping change is, I think, ever adopted as a whole. But I am struck with the reasonableness of the system of changes you propose, and the fitness of many of the special terms you have suggested.

The last thing an old teacher wants is, as you know full well, a new set of terms for a familiar set of objects. It is hard instructing ancient canine individuals in new devices. It is hard teaching old professors new tricks. So my approbation of your attempt is a *sic vos non vobis* case so far as I am concerned. There is one term which I do not quite fancy, *pero*, which you couple with *pes* in naming the rhinencephalic lobe. I should prefer the old term *bulbus* with *theca* unless there is some objection I do not see.

What you have to do is to keep agitating the subject,

to go on training your students to the new terms—some of which you or others will doubtless see reasons for changing—to improve as far as possible, fill up blanks, perhaps get up a small manual in which the new terms shall be practically applied, and have faith that sooner or later the best part of your innovations will find their way into scientific use. The plan is an excellent one, it is a new garment which will fit Science well, if that capricious and fantastic and old-fashioned dressing lady can only be induced to try it on.

Always very truly yours,

O. W. HOLMES.

A CURIOUS EGG.

E. E. BARNARD.

One of my hens of the "Dominico" breed is accountable for the presence to-day of a most remarkable egg, which was found in the hen's nest. This singular object measured about three inches in its longest diameter, a round oval in shape, not like the ordinary egg with a large and a small end. The shell was thin and soft to the touch, resembling the "skin" that is found inside an eggshell. Pressing on one end of the egg, a hard object was felt inside the shell. Opening the egg, by cutting with a sharp knife, two eggs were found, one perfect with a hard shell, slightly smaller than the ordinary egg, the other perfect in every respect, save that it possessed no shell. The egg with the shell was enclosed in the white of the other. These two eggs occupied the two ends of the original shell. Upon opening the one with the hard shell it was found to be perfect. Putting the two eggs in separate cups, the one which had the hard shell was slightly smaller and its yolk of a pale yellow; the yolk of the other was somewhat deeper in color.

Here we have a rare phenomenon; first a large egg with slightly soft shell; inside this two eggs, one perfect in a hard shell, the other without shell but otherwise perfect.

NASHVILLE, Tenn., *May* 9.

BOOKS RECEIVED.

A MEMORIAL OF JOSEPH HENRY. Published by order of Congress, Washington, 1880.

The present volume presents in a handsome and convenient form the historical facts relating to the career of Professor Joseph Henry, and a record of the various ceremonies and memorial exercises celebrated after his death in honor to his memory.

The memorial exercises at the Capital include addresses by President Garfield, Hannibal Hamlin, Robert E. Withers, Professor Asa Gray, William B. Rogers, General Sherman and others.

The concluding words of President Garfield's address may well be quoted as conveying the general esteem in which Professor Henry was held by all who knew him. "Remembering his great career as a man of science, as a man who served his Government with singular ability and faithfulness, who was loved and venerated by every circle, who blessed with the light of friendship the worthiest and the best, whose life added new lustre to the glory of the human race, we shall be most fortunate, if ever in the future, we see his like again."

NOTES.

RECENT experiments by M. Grehaut, prove that the quantity of carbonic acid exhaled by any one individual of an animal species is about constant. Fifty litres of air passed through the lungs of a dog, 9kg. weight, yielded 2.747 gr. of CO_2. Eight days after the experiment was repeated, and the CO_2 was 2.810 gr. In man, the same volume of air circulating through the lungs, receives 3.333 gr. of CO_2. Irritations and inflammations of the respiratory mucous membrane (*e. g.* through inhaling sulphurous acid), considerably decrease the exhalation of CO_2. The gas then tends to accumulate in the blood.

GALVANIC GILDING.—M. Rod gives the composition of a bath to be used at temperatures from 50° to 80° C. It consists of 60 parts crystalline phosphate of soda, 10 parts bisulphate of soda, 1 part cyanide of sodium, 2½ parts chloride of gold, and 1,000 distilled water. In order to prepare the bath the water is divided into three portions of 700, 150, and 150 respectively. The phosphate of soda is dissolved in the first lot, the chloride of gold in the second, and the other ingredients in the third. The two first portions are gradually mixed together, and the third is then slowly added. A platinum plate is used as anode.—*Le Monde de la Science.*

RADIATION THROUGH EBONITE.—Captain Abney exhibited at the Physical Society of London, a number of photographic negatives taken by himself and Colonel Festin by radiation through thin sheets of ebonite. The light from the positive pole of an electric lamp was sent through a thin sheet of ebonite $\frac{1}{64}$in. thick, and photographs taken showed the radiation to have a low wave-length, from 8,000 to 14,000. The carbon points of the lamp could be photographed through the sheet, and Colonel Festin observed the sun's disc through it. The ebonite showed a grained structure, and different samples of ebonite gave different results, but all gave some result, in course of time at least; old ebonite, like that used in some of Mr. Preece's experiments, scattering the light more than new ebonite. Dr. Moser exhibited the passage of the rays through the ebonite to the audience by means of a galvanometer. Professor Guthrie observed that Captain Abney had proved that light as well as heat traversed the ebonite, and Dr. Coffin stated that compositions of ebonite, apparently the same, might vary considerably.

PHOTOGRAPHIC PHOTOMETRY.—A promising application of photography to precise measurement of phenomena of light has been recently tried by M. Janssen. The method is advantageous in that photography reveals the action of the extremely weak luminous and the ultra-violet rays; but the chief advantage lies in the permanence of the results as against the fugitive nature of ordinary photometric comparisons, which, too, require the simultaneous presence of the two light sources. The various amounts of metallic deposit on the photographic plate cannot well be weighed, so M. Janssen measures by the degree of opacity produced. His photometer consists of a frame with sensitised plate, before which is passed at a known rate of uniform motion a shutter having a slit. If this slit were rectangular, a uniform shade would be produced on the plate; but by making it triangular he obtains a variation of shade, decreasing from the side corresponding to the base of the triangle to that corresponding to the apex. It is further proved that the photographic deposit does not increase as rapidly as the luminous intensity. Now, to compare the sensibility of two plates differently prepared, they have merely to be exposed successively in the frame under like conditions, and the points where they show the same opacity being compared to the points of the triangular slit corresponding to them, the ratio of the apertures at those points expresses the ratio of sensibility. Thus the new gelatino-bromide of silver plates are proved to be twenty times as sensitive as the collodion plates prepared by the wet process. Again, to compare two luminous sources, they are made to act successively on two similar plates in the photometer, and the points of equal shade in the plates indicate, as before, the relation sought. M. Janssen has compared the light of the sun and some stars on these principles, preparing from the former "solar scales" (with uniform degradation of shade), under exactly determined conditions as to sensitive layer, time of solar action, height of the sun, etc. Circular images of stars are obtained by placing a photographic plate a little out of focus in the telescope, and a series of these, got with different times of exposure, are compared with the scales obtained from sunlight. M. Janssen will shortly make known some of his results.

SCIENCE:

A Weekly Record of Scientific Progress.

JOHN MICHELS, Editor.

Published at

TRIBUNE BUILDING, NEW YORK.

P. O. BOX 3838.

SATURDAY, JUNE 11, 1881.

We have received a copy of the *Annuaire de l'Observatoire Royal de Bruxelles*—a book of nearly four hundred pages, published under the supervision of Dr. J. C. Houzeau. This number is the forty-eighth issue of the series, and contains the customary data regarding calendars; rising, setting and meridian passages of the sun, moon and planets; eclipses of the sun and moon, and transit of Mercury; occultations of stars by the moon; eclipses of the satellites of Jupiter; positions of fixed stars; elements of the planets and their satellites, and of the periodic comets; various data pertaining to weights and measures, geographical positions, etc. It is a noteworthy fact, that while the astronomical repertoire supplies a need for Belgium—as the similar *Annuaire du Bureau des Longitudes* does for France—we have no like publication in America. It must cost really very little to print it, and the expense of compilation can not be great. It is not a little remarkable that Americans generally should so long be content with dependence upon patent medicine almanacs for this class of information.

Among the appended articles, we note a few which carry more than a passing, special interest—*Le Globe Terrestre—Quel est le Climat le plus Favorable au Développement de la Civilisation?—L'Astronomie dans l'Antiquité—L'isthme de Panama.* Monsieur L. Niesten, a well known astronomer of the Royal Observatory, contributes no less than four articles to this issue of the *Annuaire*, two of which appear to have been prepared with great care, and are astronomically of much importance. The last transit of Mercury, May 6, 1878, was very fully observed everywhere, and M. Niesten deserves much credit for his well arranged digest of every sort of observation on that occasion. Those who are concerned with general relations on the rapidly multiplying group of small planets will get a deal of information from Niesten's article, *Les Astéroides*—which is, in fact, a comprehensive history of these bodies. An accompanying map serves to bring out some points which are made clearer by graphical representation. Astronomers and others will have frequent occasion to refer to an article (which it is remarkable should not have long ago been prepared by some one)—*Nomenclature des Observatoirés Astronomiques Existants, qui out la Caractére d'Etablissements Publics.* About 120 observatories are included in this list, and there are given, as far as known, the year of founding, the connection of the observatory, some brief description of the instruments, and the names of all the directors of each establishment, including the dates of their installation.

THE AMERICAN CHEMICAL SOCIETY.

The June meeting of the American Chemical Society was held Friday evening, the 6th inst., Prof. A. R. Leeds presided. Mr. A. P. Hallock was elected a regular member. The first paper before the Society was by Dr. Chas. A. Doremus, "On the Composition of Elephants Milk." The sample was obtained from the mother of the baby elephant "America" which is now on exhibition in this city. The baby weighed 213½ pounds at birth and at the end of a year turned the scales at 900 pounds. Considerable difficulty was experienced in procuring the sample, and but a very small quantity was obtainable. Three analyses were made and the figures are herewith given:

	I. April 5. Morning.	II. April 9. Noon.	III. April 10. Morning.
Quantity	19cc.	36cc.	72cc.
Cream, per cent	52.4	58.	62.
Reaction	Neutral.	Slightly alkaline.	Slightly acid.
Sp. Grav	....	......	1.0237
In 100 Parts by Weight.			
Water	67.567	69.286	66.697
Solids	32.433	30.714	33.303
Fat	17.546	19.095	22.070
Solids in fat	14.887	11.619	11 233
Casein	14.236	3.694	3.212
Sugar		7.267	7.392
Ash	0.651	0.658	0.629

It will be noticed from these analyses that the milk is peculiarly rich in the nitrogenized materials. The volume of cream compared with that obtained from an Alderney cow is also quite large. Under the microscope the milk globules appeared very uniform in size and were unusually clear. Although it is generally claimed that the fat when burned emits a peculiar odor by means of which it is possible to distinguish the animal from which it has been obtained, yet in the present instance no odor was perceptible from the fat which was separated from the milk. This is the only analysis of elephant's milk on record, and Dr. Doremus is certainly deserving of much credit for the interesting information which he has obtained. His entire paper will be published in the proceedings of the Society. An analysis of the milk of an hippopotamus is added for the sake of comparison:

Water	90.43
Solids	9.57
Fat	4.51
Casein, and milk sugar	4.40
Ash	0.11

SLEEP AND SOMNAMBULISM.*

By M. Regnard.

[Translated From the French by the Marchioness Clara Lanza.]

II.

Ladies and Gentlemen:—In the middle ages and up to the present century Somnambulists, together with epileptics and hysterical women, were classed with sorcerers and those supposed to be possessed by the devil. They were exorcised with others afflicted in similar ways and generally burned alive with great ceremony and rejoicing.

During this unenlightened era, one man of genius proved himself. in regard to Somnambulism, to be an exceptional observer and has left us a description of it which no modern neurologist would repudiate. His name, gentlemen, is upon your lips. It is Shakespeare who in his tragedy of *Macbeth* has given us a masterly description of automatism. You are all familiar, doubtless, with the sleep-walking scene, but I will recall a portion of it to your mind. After having committed her terrible crimes Lady Macbeth has attacks of Somnambulism. One of her ladies in waiting informs the court physician and both sit up at night to await the coming of the queen.

"*Gentlewoman*—Lo you, here she comes! This is her very guise; and, upon my life, fast asleep. Observe her: stand close.

Doctor.—How came she by that light?

Gentlewoman.—Why it stood by her: she has light by her continually: 'Tis her command.

Doctor.—You see her eyes are open.

Gentlewoman.—Ay, but their sense is shut.

Doctor.—What is it she does now? Look how she rubs her hands.

Gentlewoman.—It is accustomed action with her, to seem thus washing her hands; I have known her continue in this a quarter of an hour.

Lady Macbeth.—Yet here's a spot.

Doctor.—Hark! She speaks: I will set down what comes from her, to satisfy my remembrance the more strongly.

Lady Macbeth.—Out, damned spot! Out, I say!—one; two; why, then, 'tis time to do 't:—Hell is murky!—Fie, my lord, fie! A soldier and afeard! What need we fear who knows it, when none can tell our power to account?—Yet who would have thought the old man to have had so much blood in him?

Doctor.—Do you mark that.

Lady Macbeth.—The Thane of Fife had a wife; where is she now?—What, will these hands ne'er be clean? No more o' that, my lord, no more o' that; you mar all with this starting.

Doctor.—Go to, go to; you have known what you should not.

Gentlewoman.—She has spoke what she should not, I am sure of that; heaven knows what she has known.

Lady Macbeth.—Here's the smell of blood still; all the perfumes of Arabia will not sweeten this little hand. Oh! Oh! Oh!

Doctor.—What a sigh is there! The heart is sorely changed.

Gentlewoman.—I would not have such a heart in my bosom for the dignity of the whole body.

Doctor.—Well, well, well.

Gentlewoman.—Pray God it be, sir.

Doctor.—The disease is beyond my practice; yet I have known those which have walked in their sleep, who have died holily in their beds.

Lady Macbeth.—Wash your hands, put on your night-gown; look not so pale—I tell you yet again, Banquo's buried; he cannot come out of his grave.

Doctor.—Even so.

Lady Macbeth.—To bed, to bed; there's knocking at the gate. Come, come, come, come, give me your hand; what's done, cannot be undone. To bed, to bed, to bed.
Exit.

Doctor.—Will she go now to bed?

Gentlewoman.—Directly.

Doctor.—Foul whisperings are abroad; unnatural deeds
Do breed unnatural troubles. Infested minds
To their deaf pillows will discharge their secrets.
More needs she the divine than the physician.
God, God, forgive us all! Look after her:
Remove from her the means of all annoyance,
And still keep eyes upon her. So good night;
My mind she has mated, and amazed my sight;
I think but dare not speak.

Gentlewoman.—Good night, good doctor.

Gentlemen, do you not think this fine description contains all the details I previously gave you, and that Shakespeare has shown himself scientifically superior to all who have hitherto attempted to represent this singular nervous affection?

I have now finished what I had to say about natural Somnambulism and find myself confronted by the most difficult point of my subject, provoked or induced Somnambulism—Magnetism if you insist upon my employing that detestable word.

It is quite possible by means of various practices which I shall make known to you later, to produce a nervous affection very similar to Somnambulism, but yet differing from it in several ways. The effects obtained depend of course upon the subject and the methods employed, and the conditions resulting from these may be divided into three, all of them however, being sometimes induced in a single person. These three states are:

1. Hypnotism.
2. Sleep.
3. Catalepsy.
4. Automatism.

Gentlemen, during the latter part of the foregoing century an Austrian physician of great repute, seemingly, arrived in Paris. His name was Mesmer and he had discovered the means, by a purely physical process, of producing certain effects upon the human organism which were considered to be perfectly prodigious. Mesmer appeared first about the time when great excitement was being caused by the first discoveries in electricity, made by the Abbè Nollet, and when the singular action produced upon a magnetized needle by a fluid apparently permeating the earth, attracted universal attention. Mesmer announced that he was master of another fluid which was but a modification of the terrestrial one and which operated upon the vital forces, and when properly directed could become a most important curative means.

He made an offer to the government to sell his secret which he estimated to be worth several million francs. The French ministers, however, were prudent and allowed Mesmer to keep the great mystery to himself.

His method had nothing about it resembling real magnetism. His performances took place in a partially darkened room in the middle of which was placed a large tub generally covered. A number of rods were placed crosswise on the top around which the people seated themselves. Soon the sound of a piano was heard, while the atmosphere grew heavy with perfumes. Mesmer walked about the room with a prophetic air, touching the forehead of each person, and executing a series of theatrical gestures. The subjects then fell into a comatose state. They remained in ecstasy, almost entirely deprived of sensibility and movement, and only recovered under the influence of broad daylight and fresh air.

There was not a bit of Magnetism in all this. The subjects were generally hysterical women. Their imagination was greatly excited and the same thing recurred to them as now happens to those persons we hear of as being afflicted with religious mania, etc.—they were hypnotized.

*A lecture delivered before the *Association Scientifique de France.*

To Mesmer we cannot even give the credit of invention, for hypnotism or uncompleted Somnambulism or ecstatic sleep, as you choose to call it, occupies still as it did then a high place among certain religious sects. It is nothing more than *ecstacy*, where exterior comprehension is lost and replaced by a series of visions *en rapport* with the preoccupation of the subject. I will show you presently that although ecstasy is generally of a religious character, there are many exceptions and that in fact any vivid mental emotion can provoke it.

The fakirs of India frequently induce the condition, not by absorbing themselves in some holy or poetical idea, but simply by gazing fixedly at space or some bright object or spot; some of them look at the end of their nose. The Grecian monks are also celebrated for being able to produce Hypnotism by looking steadily at a certain point or thing, and will remain insensible for hours. The result of this is that they enjoy the reputation of either holiness or witchcraft, according to the form of the delirium which usually follows.

At all times that which was called *contemplative asceticism* has been produced by fixing the gaze upon some brilliant or shining object to which was attributed some particular virtue or sacredness. These contemplations, together with violent mental excitement, were rapidly succeeded by hallucinations, apparitions, and in short, ecstasy.

Mahometanism even, although not particularly mystical, has likewise produced special forms Hypnotism. A prolonged and monotonous sound in these cases was more effectual than a fixed gaze.

Among the disciples of Hussein, the martyr, ecstacy is induced by means of tambourines beaten incessantly in a rapid and monotonous manner, accompanied by measured chanting. This ceremony frequently occurs at night, and in a short time the subjects are in a state of ecstacy, in which cutaneous insensibility is so marked that all the tortures undergone by the martyr can be likewise inflicted upon them without eliciting a cry or groan.

But these phenomena are shown in still more intense a manner in the sect of Aissaoua, many representations of which can be met with in our Algerian colony. Those who have had the rare good fortune of witnessing one of their ceremonies have been struck with the degree of anæsthesia which seems to affect these people.

The ceremony takes place at night, generally in some deserted plain. The tambourines keep up a constant monotonous sound. The subjects seat themselves about an immense fire and gradually fall into a condition of ecstacy. Some of them writhe convulsively and utter prolonged cries. Anæsthesia becomes complete and then some can be seen applying their tongues to bars of red hot iron, while others eat Barbary figs, the long thorns of which come directly through their cheeks from the inside, causing their faces to stream with blood. Still others swallow live spiders and scorpions, which remarkable feats often result very seriously.

In short, all Hypnotics proceed precisely the same way, by fixing the eyes, generally squinting, upon a certain point, or else listening attentively to a monotonous sound.

These methods which have been and always are employed to produce the phenomena, are, as we shall see, quite determined.

We are indebted to Braid for the first well regulated and experimental work upon Hypnotism, and in 1841, this English surgeon, after having witnessed so-called magnetic experiments, discovered that the prolonged fixture of the eye or hearing, and not a mysterious fluid, was the source of the incontestable phenomena he had observed. Scientific Magnetism, we may say, began with Braid.

He knew a series of experiments, for the most part extremely curious, which had just been made in France by Dupotet and Puységur. These two men, who were imbued with Mesmer's ideas, had wondered if the tub were really necessary, and if the magnetic fluid we all possess could not be transmitted from one person to another. They therefore procured a number of nervous persons and endeavored by a series of motions which nowadays we designate as passes, to realize some palpable effects. By this means sleep was produced much more rapidly than by Mesmer's method. Magnetism had been effected by communication, and it exists to this day, considerably augmented and enriched by all sorts of inconceivable folly.

Braid asked himself whether passes did not constitute a simple hypnotic process, and whether the contemplation of a fixed or moving point would not produce the same result as all these absurd magnetic gestures. His experiment was crowned with success, and his subject fell into the hypnotic sleep by simply looking at a metal ball. The magnetic fluid had been overturned!

The condition formed in this purely physical manner was such, and the insensibility so complete, that Braid was able to operate upon the subjects, and even amputate their limbs. His experiments were repeated in France by Broca, Verneuil and Laségne, the same results making themselves apparent.

Unfortunately, hypnotism cannot be induced with everybody. A number of unsuccessful attempts have always been observed, and then came the introduction of chloroform and ether. Braid's experiments were lost in oblivion until a courageous French *savant*, Professor Charcot, took them up, and brought them to points, which I shall proceed to demonstrate.

But first of all, let me show you some experiments in hypnotism. Animals can be hypnotized by Braid's process as well as human beings.

Here is an old experiment borrowed from Father Kircher. I take a hen and place it upon this black table in a sitting position, its head resting on the table. I then trace a chalk line from the end of its beak, upon which its eyes are instantly fixed. I remove my hands, and you see the hen remains motionless. I can pinch it and burn it, still it does not move. If I replace the chalk line by an electric light, the effect will be still more intense. This fact is equally noticeable in man, a sudden surprise can produce the same effect. I seize the chicken brusquely and place it rudely upon the table. It is motionless, hypnotized, Preyer says cataleptic, the word is, however, of no consequence. The same experiment is very successful, you also see, with a sparrow. If the bird's head be placed beneath his wing, the hypnotic sleep lasts a very long time.

A Guinea pig can be easily hypnotized. I take one of these little animals, a female, for M. Laborde has shown that the experiment is only successful with this sex, and I extend it brusquely upon its back. You see that it remains as I have placed it without moving, and that it is insensible, for I pinch it with all my strength.

Here is another one upon whose ears I hang some brilliant bits of steel. It turns its head from side to side to look at them, and now has fallen asleep so soundly that I cannot wake it. I fire a pistol so close to its ear that its moustache is singed, but it does not move.

These animals are hypnotised; their condition consists in a total loss of sensibility. But they are not asleep, they do not dream, they are not somnambulists.

Hypnotism can be produced in almost any one who makes himself perfectly passive. But if you experiment upon one of those persons whom we call hysterical you will obtain quite a different condition. The same means bring you to *artificial somnambulism*. The difference in the subject produces the difference in the effects. Here it is that M. Charcot's experiments and the Salpêtrière investigations begin, in which I was kindly permitted to assist.

I must first of all tell you what a hysterical subject is and what constitutes the principal phenomena she presents, for we shall see that her condition of Somnam-

bulism is a mere modification, sometimes a simple reproduction of them.

A hysterical woman at first sight cannot be distinguished from any other, unless we except a rather strange expression of face and a peculiarity of dress. These persons always cover themselves with several loud colors which do not harmonize in the least. I shall soon tell you the reason of this.

The first thing to be observed in them is *anæsthesia;* hysterical women are sometimes paralyzed on one side of the body and sometimes on both. They can then be pierced with long needles without feeling anything whatever, and fall into all sorts of singular errors as one side of their body seems to be dead. They do not know where their arms or legs are unless they look at them. Sometimes they allow themselves to be burned without percieving it. One day, a hysterical patient at La Salpêtrière found a hole in the stocking she was about putting on. She sewed it up, and walked about all day. On going to bed that night she was unable to remove the stocking, and on calling for help it was discovered that she had sewed it to her foot.

A French physician, M. Bureq, has shown that the application of metal to the insensible parts render them sensible. This is called *metallo-therapy*, and singularly enough, the committee who examined this phenomenon affirmed that while sensibility returned to one arm, for example, it disappeared in the other at precisely the same point, so that the subject was in no wise benefited.

Anæsthesia of the skin also extends to the other senses. Hysterical women do not hear well, their sight is defective and, generally speaking, they are unable to distinguish colors; sometimes with one eye and often with both they are *achromatopsic;* everything looks gray to them. Their senses are therefore in a state similar to sleep, from which certain exciting influences such as metals, electricity, etc., can rouse them temporarily.

Their muscles are frequently paralyzed. There is nothing in fact, more common than a hysterical paralytic. Sometimes the muscles are violently contracted, and remain thus for years. An intense emotion can suddenly stop the paralysis in contraction. I need not tell you how this is achieved.

These contractions also, can be induced easily. It is only necessary to rudely sieze the arm of a hysterical woman and it will remain contracted in whatever position you place it. In short, these people have periodical attacks in which they reproduce nearly everything that we can obtain from them by magnetism.

When a hysterical woman is about to have one of these attacks, the first thing she experiences is a certain uneasiness and discomfort, as though a ball rose from her stomach and remained stuck in her throat. This is nothing more than muscular contraction of the œsophagus. Suddenly, she utters a loud cry and falls backwards. Her eyes roll wildly and a sort of foam appears upon her lips. Simultaneously, her arms are violently extended and her clenched hands turned towards the inside. The entire body becomes as rigid as in an attack of Tetanus. Then the patient utters a prolonged scream, bends her body in the form of an arch in such a way that her weight is sustained solely upon the head and heels. This period is succeeded by all kinds of disordered movements which last from two to three minutes. Then contraction begins. Sometimes the whole body contracts, sometimes only a portion. In this way, the contraction of the arms frequently places the patient in the attitude of the crucifixion and this last generally for days accompanied by complete insensibility. Then intervenes a period of repose. One would say that it was all over and that the patient slept. But indeed it is but the beginning of the final and most interesting period of all, the ecstasy which M. Charcot has termed *attitudes passionnelles.* The patient absolutely ignorant of all her surroundings, neither perceiving sound or light, begins to follow out a dream which has the peculiarity of being always the same and is the reproduction of some event, or series of events, belonging to her existence. My friend M. Bourneville, physician to L'Hospice de Bicêtre, and myself have published a book wherein all these facts are minutely described. It is called the *Sconographic photographique de la Salpêtriere* and comprises the entire study of hysteria as well as Somnambulism. The descriptions are completed by a series of pictures produced by an instantaneous photographic process, and these I shall now proceed to show you.

In the *attitudes passionnelles,* the hysterical patient is really a spontaneous and automatic somnambulist. You will now understand why it will be so easy presently to put her in a condition of artificial Somnambulism. I will show you some *attitudes passionnelles.* The patient sees some frightful object as you may imagine by her terrified position. But see, her features relax and here we have religious ecstasy. Once more the scene changes to give way to this when she keeps time to music which she thinks she hears.

The young girl represented in these photographs has been subject to these attacks for six years. Her hallucination or dream has never changed in a single detail, and there are a hundred more precisely like her in Paris.

Gentlemen, you will probably ask if this terrible disease, so much talked of at the present day, is new—if it is a production of this "nervous century," if I may so express myself, or whether it is of ancient date. My reply is a simple one. Hysteria is as old as humanity itself. No matter how far back you may travel in the history of the world, you will always find it. What, indeed, were the pythonesses, the ancient sibyls, the sorceresses and possessed of the middle ages, if not somnambulists and hysterical women? The descriptions of their paroxysms cannot leave us in doubt, for their characteristics are plainly shown. Do we not know that they were pricked and burned without being aware of it. And did not this very fact prove that the devil had set his stamp upon them, and did it not invariably result in their being butchered alive? Better still, painting assists us to form a vivid impression of these attacks. Look at the "possessed" which figure in the works of Rubens, Raphael, Jordaens and Breughel, and you will immediately recognize the attitudes which I have just shown you in the photographs. Here are some copies of these famous pictures. Look at them and see if you can doubt for a moment.

This long diversion I have made purposely, that you might fully comprehend the precise ground upon which we stand. The means employed to produce Hypnotism can induce hysterical manifestations similar to those produced spontaneously. These manifestations are *artificial Somnambulism, Catalepsy* and *Automatism.*

To provoke Somnambulism requires a very simple mode of operation. It is the same as that employed to induce Hypnotism. You can make the person fix her eyes upon a bright object. Ordinarily, however, you seat yourself directly in front of her and tell her to look at you steadily. After a minute or two has elapsed, you see her eyes assume a vague expression, then fill with tears, and finally, in a short time, varying from a minute to a quarter of an hour, according to the subject, they close, the head falls and sometimes a little foam appears upon the lips. Sleep is produced, real sleep accompanied by total loss of sensibility. This is, therefore, more than Hypnotism.

If the subject is restless, her thumbs can be held in the closed hand. As for passes, I have always observed that they retard the sleep instead of promoting it. M. Richet, on the contrary, places great faith in these movements.

You see, gentlemen, that nothing can be more simple. A little patience the first few times and the thing is done. There is no fluid, be it understood; the *magnetizer* has

nothing individually to do with the phenomenon. All that takes place originates with the *subject* whose brain is actually annihilated and brought to such a condition that any dream can be provoked by *suggestion.* We have in fact, an automaton similar to that which I called your attention to in Natural Somnambulism, only while the latter merely obeys the impulse of memory, the former is subject to our will.

Hypnotism can also be produced by simply placing the thumbs gently upon the closed eyelids of the subject, allowing the hands in the meanwhile to rest upon his temples and press upon the eye-balls. This process is very effectual with some subjects. A person accustomed to be hypnotized can be put into the condition by having some one shout suddenly and authoritatively in his ear, "Sleep!" A theatrical gesture accompanying the command makes it more effective. The Abbé Faria, a celebrated charlatan who completely mystified the world about twenty years ago, always adopted this method. The other ways, however, are preferred at La Salpêtrière, and also at Breslau by the well-known Professor Heidenhaim.

All that I have just said refers to the first experiments made with subjects. After they have once been hypnotized, however, the state can be induced much more easily. Here it is that Imagination steps in and mountebanks are allowed the utmost liberty of action. The mere idea that he is about to be put to sleep causes the subject to fall asleep almost immediately. If, in addition, he is made to think that the operator possesses some secret influence, or supernatural power, you will soon see what may happen.

A patient at La Salpêtriére, who had firmly persuaded herself that I had a peculiar influence upon her, fell into a hypnotic condition every time she saw me, independent of the locality. She often became hypnotized upon the staircase or in the middle of the courtyard. One day some one said to her jokingly that she could be hypnotized simply *by the will* in the midst of a public ceremony which was to take place a few hours later, and she actually refused to appear on this occasion so fully was she convinced that what had been mentioned would really occur. In such cases, the imagination is everything. The subject alone is responsible for all that happens. A few examples will make you thoroughly understand what I mean. I have actually succeeded in persuading patients that they could not leave the room because I had magnetized the door-knobs. They would hesitate for a long time before approaching them, and ss soon as they touched them they became hypnotized. Need I tell you that nothing whatever had been magnetized? This experience is important, for by means of it we can explain cases in which the subjects fall into the condition while drinking a glass of *magnetized water*, or while lying down beneath a *magnetized tree.*

Magnetic experiments made at a distance belong to the same category. How often we have read of magnetizers who have succeeded in putting subjects into a deep sleep while the former is in one room and the latter in another. Here again the subject alone is the agent, I have frequently tried this experiment. A patient named P—— was told, "M. Regnard is in the next room and he is magnetizing you." She would instantly exhibit great uneasiness and then fall into a deep sleep. This even happened when I was not in the next room or even in France, and when, I am free to confess, I was thinking of anything rather than her.

On another occasion I said to a patient that I would magnetize her at three o'clock in the afternoon, and ten minutes after making this remark I had forgotten all about it. On the following day, however, I learned that she had fallen asleep precisely at three o'clock.

The immense number of absurdities which go to compose magnetizer's guide books can be explained in this way. The imagination of the subject is vividly affected and sleep is produced subjectively and without the intervention of any exterior influence. No matter what manner of *Magnetism* is employed the result is always precisely the same—the subject remains inert.

Different peculiarities are then observable, the most important of which is hyper-muscular excitability. In a normal condition our muscles are very susceptible. Any violent check causes them to contract, and the same effect is often produced by reflex action.

In artificial Somnambulism, the action of the spinal cord being no longer moderated by the brain which is annihilated. the muscles contract by reflex action beneath the very smallest influence. Pass your finger as lightly as possible over the forearm of a sleeping hysterical woman and you will immediately perceive muscular contraction. Charlatans obtain this effect by gently touching the muscles while apparently only making passes. By causing the muscles of the back to contract subjects can be made to assume positions which appear incompatible with the equilibrium. Here are a couple of photographs taken of two somnambulists. One of them, you see, has her head thrown back until it nearly touches her waist, while the other rests with her feet on the back of one chair and the nape of her neck on the other, her body bent in the form of an arch. I show you these two positions, so frequently exhibited by would-be performers of miracles, simply that I may explain to you how I obtained them.

All the results reached so easily in magnetic sleep are nothing more than hysterical muscular contraction. This can be proved by the fact that if the patient is awakened during this state, the contraction remains indefinitely, and in order to remove it she must be put to sleep again, and antagonistic muscles contracted.

The study of this important branch of the subject led M. Charcot and his students to the investigation of a most curious thing, and one which has helped to calm the fears of people, who, without witnessing the experiments performed, denounced the whole affair as an imposition.

Gentlemen, there are about two thousand persons in this room. With the exception of a few physicians who are present, it is probable that none of you know the action of the muscles as described by Duchenne, of Boulogne, nor yet the distribution of the nerves situated in the arm. Do you believe that a girl who can neither read nor write, and who comes from the most obscure portion of Brittany, could be versed in the details of this delicate physiology? For my part, I do not believe it. If she is an imposter, we shall soon discover it. Here she is; let us hypnotize her, and then excite the cubital nerve at the elbow, and see if she makes a wild gesture. Not at all; she merely bends her little finger, the third finger and thumb. The cubital nerve therefore, only affects these three fingers. Many medical students of my acquaintance are ignorant of this fact. Let us now excite the sterno-mastoid muscle, this diagonal cord which appears upon the neck when the head is turned. You see, she turns her head towards the opposite side. Better still, let us excite the face muscles with this pencil, and you perceive the same effects appear as were obtained by Duchenne with electricity, such complex effects, too, that even physiologists have difficulty in remembering them. If this girl is only pretending, she is exceedingly clever. I shall have finished my remarks upon sleep, after having told you that it is quite possible, at this period, to make the subject rise and follow you, and utter loud cries, should any one come between you and her.

The second state which can be produced by Hypnotism upon hysterical subjects, is Catalepsy. This *bizarre* condition, of which I shall attempt to give you an idea, exists normally in the patient, and the processes employed only serve to develop it. Sometimes it appears without any provocation whatever. Nothing is easier than to make the subject pass from a sleeping state to a cataleptic one. It is only necessary to open his eyes suddenly, and he will then remain as though transfixed. His eyes assume a

set stare, and whatever attitude you cause him to take, he will remain in indefinitely. He can be placed in the most trying postures, and he will stay just as you have put him, and as long as you choose. I have here some photographs of several people taken while they were in this state. You can see how impossible and extraordinary the postures appear, and how they can be maintained for a great length of time. I may say, however, that nothing can be easier than than this kind of photography. The subjects never make the slightest movement, and it is even pretended that the celebrated sculptors of antiquity made use of cataleptics as their models. This may not be true, but it is quite possible.

There are other ways of inducing Catalepsy. Do you recollect the process generally employed to produce sleep? It was the sight of a brilliant object, or the prolonged noise of a monotonous sound. The same means are physically made use of to induce catalepsy. Let us suppose, for instance, that a hysterical subject is made to listen to the prolonged vibrations of a single octave struck upon the piano. Nothing is more irritating than this monotonous sound. The subject rapidly falls into a cataleptic state, and singularly enough, remains in it as long as the octave is struck. As soon as the sound ceases however, the catalepsy disappears.

What is thus produced by a sound can also be caused by intense light. Here are a few subjects whom I will place directly in front of this electric light. You see they become cataleptic instantly. If the light is extinguished you perceive they will fall backwards into a non-cataleptic sleep. A sudden noise or an instantaneous flash of light can produce the phenomena equally well. I remember witnessing a curious scene one day at La Salpêtrière. It was during some public ceremony, and a military band was playing in the court yard of the establishment. One of the patients under the care of M. Charcot listened to the music with the most intense delight. Suddenly there came a clash from the brass instruments which made us all tremble, but the patient fell into a cataleptic state and had to be carried from the room. A short time after another patient went during a holiday to a concert. No doubt on that occasion the musicians performed some "music of the future," for the patient suddenly fell into a cataleptic condition, and had to be removed.

It is very easy to reproduce these phenomena. It can be done by beating a Chinese gong unexpectedly in the subject's presence. You all know what a disagreeable sound it is. The patient makes a gesture of fright and remains rooted to the spot in a state of catalepsy. A sudden explosion of gunpowder is equally effective. I must tell you however, gentlemen, that this last experiment has its disadvantages. Catalepsy produced in this way often terminates with an attack of hysteria. On one occasion it was followed by a sort of frenzy which lasted five days and then stopped spontaneously.

While in a state of catalepsy the subject is not cognizant of his surroundings. He neither sees nor hears, neither does he speak, differing in this latter respect from the somnambulist or hypnotic subject. The muscles, moreover, are not hyper-excitable. It is singular, however, that while in this condition it is exceedingly easy to provoke automatism by *suggestion*. Take for instance a cataleptic subject. Place him in an attitude expressive of anger, love, expectation or prayer. His face will immediately assume the expression required to complete the effect.

The second degree of automatism is a little more complicated, and will recall to your mind the effect obtained with somnambulists when an idea suggested to them produces others. Veritable hallucinations can be formed in this way.

To obtain this result, place yourself in front of a subject who is in a cataleptic state and endeavor to attract his attention. This is the difficult point inasmuch as nearly all his senses are annulled. When you have succeeded, however, make a motion for example, as if you were trying to catch a bird. This gesture will immediately suggest an idea to the subject and be followed by a series of conceptions. The catalepsy ceases instantly and is succeeded by automatism. The subject rises, begins to run rapidly. His mind gradually wakens, a dream commences and generally speaking nothing is more curious than to watch its development. Sometimes he appears to be fleeing from a serpent, at others from an apparition, and so real do the hallucinations appear to him, that he would dash through a glass door or out of a window while attempting to escape from or follow his illusion. I may add that if the act suggested be quickly realized, the subject will repeat it indefinitely. If I place a cake of soap in his hands he will go through the motion of washing them interminably. One patient that I had continued for three hours and would have gone on still longer had I not stopped him.

I have shown you how you must proceed to induce the condition. Now I must tell you how to dismiss it. It is very simple. Magnetizers make passes, physicians merely tap the subject's cheek lightly with their fingers, or sprinkle a few drops of water upon the face. I must also tell you that it is not desirable or prudent to allow the state to continue for a long time. Two subjects I have seen nearly died in consequence of remaining in a cataleptic condition twenty-four hours. Respiration nearly ceased, the heart beat almost imperceptibly and asphyxia followed. Death, undoubtedly was not far off.

Gentlemen, I am done. I have told you all that I know, all that I have seen in regard to this famous *animal magnetism*. I have said nothing, however, about reading with bandaged eyes or by means of second sight, nor have I spoken of divination or the art of curing disease by magnetism. Such things have no place in Science. They are not mentioned at Sorbonne. Our asylums of Bicêtre and Charenton, or our court-rooms seem to me the only places where they may be discussed from time to time.

After all it is not, perhaps, astonishing that such *bizarres*, physiological facts as those I have just demonstrated, should have tempted charlatans and deceived imbeciles.

Before I leave you, gentlemen, let me tell you what I fear and what I wish.

I fear that while speaking to you so earnestly about sleep I have performed my best experiment. Do you recollect?—words succeeding words like the monotonous tic-tac of a clock, and only when the sound ceases does the audience awake with a start.

But away with this fatal thought, and allow me to tell you what I wish. I hope that I have succeeded in convincing you that all the astounding facts connected with Magnetism and Somnambulism are merely pathological exaggerations, diseases of sleep. That they are absolutely determined, that they can be produced when and how we choose upon particular subjects, without any magnetic fluid and without the aid of superior or supernatural forces. If I have persuaded you upon these points, I have destroyed one of the most laughable superstitions which still exist in the world, and this evening cannot be considered as thrown away as concerns either you or me. For my part, I shall always look upon it as one of the happiest and most profitable of my life.

VOLTA'S BATTERY.—To render Volta's battery constant and depolarized, Count Mocenigo fixes twelve couples with their elements on a horizontal axis, a trough of acidulated water having twelve compartments is then brought up by a lever motion so as to cover a good third of the surface of the battery, and a rotatory movement is communicated to the axis.

FOSSIL ORGANISMS IN METEORITES.*

By Geo. W. Rachel.

Dr. Hahn's work, of which "SCIENCE" gave a short notice in its last issue, promises to revolutionize many views which have heretofore been believed to be firmly and irrevocably established. It is not at all necessary to accept all the conclusions and agree with all the various lines of reasoning, into which the author has been led by his results, but nobody will fail to perceive the portentous meaning of the results with which his untiring efforts in this important matter have been rewarded.

There has been formerly a manifest tendency to belittle small things and apparently insignificant phenomena, and bestow the greatest attention on those matters which impress the observer by their magnitude. Modern science has done away considerably with this erroneous method and has taught us that it is the little things which achieve great results in nature, as a rule. To this class of phenomena, which has been habitually underrated until a comparatively recent time, belong the meteorites, shooting stars and meteoric dust generally. Chladni's view that they fall from the skies, pronounced in 1795, was ridiculed by the learned men of the times. One member of a committee sent by the French Academy to investigate the fall of a meteorite in the neighborhood of L'Aigle, Le Luc, declared that he would really be forced to believe what the people who witnessed the fall said, if he did not know that such a thing was *utterly impossible*.

It was not long, however, until the celestial origin of these bodies was universally recognized, several other falls of large meteorites occurring during the first decade of the present century, which could no longer be explained away. After this various stones that were known to have fallen upon the earth were examined and described, and a good many more which were recognized to be of celestial origin. The number of all the various specimens thus investigated has gradually become very large. Kesselmayer, in his great work on the subject, describes 647 distinct falls.

It is not now necessary to recall the several results of these investigations, nor to describe the peculiar properties of meteorites on which the resemblances and differences between those celestial minerals and our terrestial rocks are based. Suffice it to state that between the two types which have been recognized, viz: those consisting exclusively of iron, and those which are composed of certain silicious minerals, such as Augite, Bronzite, Olivine, Anorthite and other Feldspars, there are all the possible combinations of both; the ferrous meteorites predominate, however, those with a considerable percentage of silicious constituents being comparatively rare, and the purely silicious still more so.

It is the latter, the silicious material, which has been examined with such remarkable results by Dr. Hahn. This occurs usually in light-colored spherical or pear-shaped masses (χονδροὶ) similar to the nests of crystals (druses) which are a well-known occurrence in crystalline rocks. These peculiar forms consist principally of Bronzite and Enstatite, which to the naked eye show an appearance graphically described by Kesselmayer twenty years ago.

Prof. Gümbel, of Munich, in a report made to the Royal Bavarian Academy of Sciences has described them, on the basis of Kesselmayer's book and his own researches, as follows:

"Longitudinal sections show columns and fibres, composed of small polyhedra, which in cross sections look like irregular polygons. These polygons often show a sort of radiating arrangement in their interior, issuing from what appears to be an ill-defined nucleus; this nucleus seems to have been changing its place gradually, for the radii show an irregularity such as would be produced by such change of site. The fibres, for that is what these structures look like, are not of equal size throughout, but taper off into points and occasionally even send off branches. This is especially visible in cross-sections where one set is apparently replaced by others, these in turn by others, and so on. All the fibres consist, as has been stated, of a light centre, and a dark enclosing substance."

This description was given in 1878, and it certainly reads like what Hahn has proved it to be: *fossil organisms!*

This successful amateur, for such he was before he succeeded in gaining his present reputation by his participation in the debate on the "*Eozöon canadense*," and then resigned his government position to pursue this peculiar line of research at his leisure—this "Gerichts-Referendarius, a D." has by an ingenious application of the comparatively new method of making transparent sections of these meteorites accomplished results of which many a specialist might be proud. In order to exclude the error to which human vision and draughtsmanship might be liable, he has prepared photographic reproductions of his specimens, and on 32 excellent plates he presents the scientific world with 142 of these highly interesting preparations. Most of the fossil structures thus revealed belong to the animal world, indeed, Hahn himself professes that he is unable to find evidences of vegetable organisms; these, however, since the appearance of his work in February, have been recognized by Prof. Karsten, of Schaffhausen, Switzerland, in sections prepared by him from a portion of the very meteorite in his possession which has furnished a considerable number of Hahn's specimens. Two of these Prof. Karsten has drawn, and the cuts are published in an exhaustive paper on Hahn's book, together with his own observations and those of others on this very subject in the German Journal "Die Natur," edited by Mr. Karl Mueller, of Halle, Prussia.

As to the genuineness of Dr. Hahn's discovery there can be no possible doubt, and it has been generally admitted—reluctantly by some, it is true—that these "Chondrites" consist almost exclusively of fossil organisms. Dr. D. F. Weinland, a member of the Academy of Sciences, of Philadelphia, where he formerly resided, has also published a review of Hahn's book in the "Ausland," edited by Friedrich Von Hellwald, of Tübingen, Wurtemberg, in which he states that by the kindness of the author he has had the opportunity of examining these specimens, and although this examination has not given exactly the same results in regard to the determination of the particular kind of organism, he cheerfully admits that they are organisms, and this fact will not be doubted by any one who scans the plates published by Dr. Hahn.

In a postscript to this review, Dr. Weinland informs the reader that the author has entrusted to him the difficult task of classifying all the fossil organisms in more than three hundred of his specimens—of which Hahn has prepared over six hundred—and Dr. Weinland who is a competent naturalist, gives a few of his preliminary results. He compares the material which these sections display to the detritus of which the youngest coral lime and sandstone (coralline crag) consist such as is found on the shores of the Mexican Gulf. He furthermore states that complete forms are rarely found, but that the material is sufficiently abundant to construct many complete species, in the manner usually applied to fossil remains.

The number of the various species of polypi, crinoids, spongiæ and algiæ which are united by a silicious material, Dr. Weinland estimates after a cursory examination at about fifty.

One of the corals is set down by various observers as

* Hahn, O. Die Meteorite (Chondrite) and ihre Organismen; Laupp; *Tübingen*, 1881, with 32 photolithographic plates.

resembling to the *Favosites Goldfussi* * from the Silurian *Grauwacke*,' another is compared to the *Calamopora Naumanni* from the same strata.

The structure of these corals is excellently preserved; the columnar structure, the stomata, the rays in the cells, indicating the partitions between the columns in cross-sections, in short, all the various parts can be perfectly well demonstrated.

Of Spongiæ Dr. Weinland has already determined three different genera. Of a peculiar bluish-colored sponge he says he could draw a perfect picture, so numerous are the various longitudinal and cross-sections in which it occurs, it would be as easy as it would be to draw it from a living sponge.

Algæ have also been recognized as forming part of this intricate network of fossils. Dr. Weinland has determined several as belonging to the *Cocconeïs*, while Prof. Karsten describes others belonging to the genera, *Leptothrix*, *Leptomitus* and *Hysterophyma*. (The latter gentleman reminds the reader of the fact, that Reinsch has lately demonstrated the existence of these and other Algæ in coal, some of his specimens containing as much as twenty per cent of such organisms.

But what is the most interesting feature of all the organisms thus ingeniously and unexpectedly brought to light in meteorites is their Lilliputian size. The coral-tree, above referred to as a *Favosites*, presents itself to the naked eye as a white spot on the section, not larger than a pin's head. Its greatest diameter measures nine-tenths of a millimeter, and the single cells not more than about five one-hundreths of a millimeter. All the other organisms detected show the same pygmean proportions, the spiculae of sponges. for instance, being absolutely indefinable to the naked eye.

The origin and formation of these celestial fossils could not possibly have been different from what we know it to be with our terrestrial specimens. They tell us of a planet, on which aquatic life was sufficiently developed to produce them and to preserve them after death by a process of infiltration with silicious material, which dissolved the lime of which these structures must have consisted as far as their inorganic constituents are concerned, and supplanted it by the various kinds of silicious minerals, filling up also the interstices and openings which had formerly contained organic substance. This planet, therefore, must have had a comparatively long period of existence; it must have had an atmosphere and its surface must in whole, or in part, have been covered by water. What the cause has been of its destruction and its utter disintegration we are, certainly, unable to tell; but the meteoric stones which formed part of it have happily crossed the orbit of our planet and thus enabled us to divine its history, at least in part.

In connection with this subject, it may not be amiss to give a short synopsis of the history of our knowledge of organic constituents in meteoric stones.

The first to detect the existence of organic substance in meteorites was the great Woehler. In the meteorite which fell on April 17th, 1857, near Kaba in Hungaria, he found unmistakable traces—while analyzing it—of a combination of Carbon and Hydrogen. Then the fact was remembered that on Oct. 13th, 1835, a fire ball had exploded in the neighborhood of Bokkeveld, Cape Colony, scattering a great number of soft, black stones over the fields, weighing, as far as could be judged, several hundred pounds. These stones emitted a strong ammoniacal smell and were found to be impregnated with water and bitumen. Woehler obtained one of these meteoric stones and found that it contained, besides one and two-thirds per cent of carbon, a quarter of one per cent of organic matter proper.

* A drawing of this fossil coral is given by DANA in his *Textbook on Geology*, on page 111. (Ed. 1868.)

Referring to this discovery, Friedrich Mohr* wrote, sixteen years ago:

"This is sufficient proof that there was present in this meteorite a carbo-hydrate similar to our ozocerite, idrialite, seberrerite, mineral wax, etc. According to our terrestrial experience we must therefore conclude that on the planet of which they formed part, there must have existed organisms, at least plants, which are the real cause of the many deoxidized combinations which we find in meteorites. The existence of plants would evidently condition the presence of free oxygen, which does not speak against the presence of these products of deoxidation, since the plants themselves require oxygen for completing their cycle, in so far as they are ultimately (by decomposition), re-transformed into carbonic acid, without which condition a long, unbroken chain of vegetable life would be inconceivable. But the water must be liquid in order to act, and this implies that this planet must have had a certain size to enable it to be sufficiently warmed by the sun. The small meteorites, as they come to us, must in spite of their being exposed to the sun's rays, have the temperature of cosmic space, since they are, just as are high mountain peaks, too insignificant to become heated by insolation alone. Only an enlargement of size enables a celestial body to develop heat enough to produce a warm atmosphere. This circumstance supports strongly the view, that meteorites have not been formed independently, but that they have formed part of a larger body, on which processes, similar to those obtained on our planet, have been going on."

This is certainly interesting reading to-day, knowing as we do that the planet in question has also been an abode of animal life.

Other meteorites containing organic substances have been recorded since then. Thus at Orgueil, France, 1864; at Knyahinya, Hungary, June 9, 1866. This phenomenon is the most important since very many of the most convincing specimens, prepared by Dr. Hahn, have been obtained from a stone weighing 27 lbs., which formed part of the 600 lbs. that fell in that particular locality on that day.

The most curious meteoric shower, however, was observed in 1870 in Sweden. Black pieces, consisting almost exclusively of mold, descended on a snow-field, and could thus be easily collected. Mold is always the result of some organic process, and living particles play the efficient part in its production.

Since bacteria are known to be able to withstand a temperature of —100° C, without losing vitality, the Thompson–Richter hypothesis of the propagation of life through the universe in this manner becomes almost a tangible reality. But, we forbear! The perspective opened by Dr. Hahn's discovery is too grand to be discussed in the brief space, allowed this notice. It is only to be regretted that the favored discoverer seems inclined to tamper with his good fortune in so far as he draws conclusions from his newly established facts which few will be willing to admit. He thinks it possible that the formation of living matter may have begun in cosmic space, that cells were developed from Chaos and a certain vegetative process could have gone on in the gaseous and liquid masses supposed to have been the formative matter of our sola-system, etc. Prof. Karsten is even of the opinion that meteorites might form in the upper strata of our atmosphere. As proof he adduces the few recorded showers of polygonal hail-stones and especially the two cases of ice-meteorites. On May 28th, 1802, there fell near Puztemischel, Hungary, a block of ice weighing 1200lbs. and Hayne in his "Tracts historical and statistical on India" reports the fact that near Seringapatam a mass of ice fell from heaven, as large as an elephant, which took, in spite of the tremendous heat, over two days to melt.

**Geschichte der Erde*, 1866, p. 500.

If we should be asked our opinion as to what the origin of these ice-meteorites may have been, we should be inclined to answer that they are very probably a small part of the collections of water (oceans?) which, we know, must have existed on the disintegrated planet to which our stone and iron-meteorites once belonged.

The various theories which have been held to explain certain well-known facts about meteoric bodies, notably Schiaparelli's ingenious hypothesis connecting comets with meteorites, the fact that most comets give a spectrum, closely resembling that of carbon, and many others will have to be revised in the light of this discovery, and it may be safely claimed that Dr. Hahn's book will prove to be one of the most important contributions to natural science of the present time.

ASTRONOMY.

Prof. Mark W. Harrington, of Ann Arbor Observatory, announces, in a private letter to the editor, the variability of star D. M. + 0° .2910, the position of which for 1855.0 is

A. R. 12h. 6m. 28.4s. Decl. + 0° 23.5′

It reached its minimum on May 22 or 23, when it was of the magnitude of D. M. + 0° .2914, which is given by Argelander as 8.7. It is now increasing in brightness at the rate of a tenth of a magnitude a day. The star, in the same right ascension and in 15′ south of the variable (D. M. + 0° .2911), is of a fine orange color, and should be put in the list of red stars.

Observers desiring information, charts, or comparison stars, for use in observing the variable, will be cheerfully assisted by Prof. Harrington or the editor.

M. Eugene Block, of the Observatory of Odessa, Russia, has communicated the following observations and elements of Comet (a), 1881, Swift:

Odessa M. T.	App. α.	App. δ.
1881 *d. h. m. s.*	*h. m. s.*	° ′ ″
May 4 14 50 15	0 15 26.53	+ 33 25 3.7
5 14 28 12	0 19 1.00	+ 32 24 36.7
7 14 36 2	0 26 35.05	+ 30 15 5.9

ELEMENTS.

$T = 1881$, May 20.8294.

$$\begin{aligned} & \quad\ ^\circ \quad\ ' \quad\ '' \\ \pi &= 299 \ \ 47 \ \ 53 \\ \Omega &= 123 \ \ 59 \ \ 25 \\ i &= \ \ 79 \ \ 33 \ \ \ 0 \\ \log.\, q &= 9.76570. \end{aligned}$$

The comparison with the middle place gives

Obs. $- c$, $\delta\lambda \cos.\beta = -27''$
$\delta\beta = +\ 3''$

Careful search has been made at Boston, at Cambridge by Mr. Wendell, at Clinton, N. Y., by Prof. Peters, and by others, for Barnard's Comet, but without success.

SCIENCE OBSERVER,
Special Circular No. 13.

BOSTON, *June* 2, 1881.

UNDERGROUND WIRES IN PARIS.—The Municipal Council of this city are contemplating adding to their funds by taxing wires placed in the sewers. The proposed tax will be 20fr. per kilometre up to 500, 30fr. from 500 to 1,000, 40fr. from 1,000 to 1,500, and so on, with an increase of 10fr. for each 500 kilometres. *L'Electricité* says that the number of kilometres of wire placed in the sewers being about 7,000, the Compagnie des Téléphones will have to pay something like 59,500fr. It adds that the company make no objection to this tax.

BOOKS RECEIVED.

SECOND REPORT OF THE UNITED STATES ENTOMOLOGICAL COMMISSION, for the years 1878 and 1879, relating to the Rocky Mountain Locust, and the Western Cricket, etc., with illustrations, Washington 1880.

This volume will be read with interest by naturalists, and the facts and statistics relating to the ravages of locusts, and the laws and characteristics governing their migrations are very complete.

The interesting chapter entitled "The Brain of the Locust" opens with these lines. "In order to appreciate the habits, migratory, reproductive, etc., of the locust, and to learn something of its general intelligence as an insect, and as compared with other insects, it is necessary for us to study with a good deal of care the organ of the locust's *mind, i. e.*, its nervous system, comprising its nervous centres and the nerves arising from them. The present chapter will be devoted to a study of the brain."

It may be confidently affirmed that with methods far subtler and reasoning much more profound, than any employed by the author of this chapter, we shall always fail to find in the structure of the nervous system any explanation of the migratory and reproductive or of any other habits *as habits* in any animal. A large wing-ganglion means a flying insect—of course, a large optic ganglion means that vision is a powerful sense in the animal in which it is found; an atropic olfactory bulb, in man the monkeys and seals, means that the sense of smell does not play so important a role in these animals as in the fox, dog, lion, camel and opossum, where the bulb is large. The preponderance of the brachial enlargement of the cord in the mole and bat is related to the preponderance of the anterior extremities over the posterior in these animals, but it no more serves to explain the difference in psychical habits existing between the two, nay it does so to a less degree even than the external structure. There are species of locusts which are not migratory and a study of their brains should be made if Mr. Packard wishes to draw inferences as to habits from the cerebral structure; in other words, if he would trace out the line of demarcation between a "migratory" and a "non-migratory" brain.

We believe that the clause in question has been inserted with the purpose of indicating that there *is* a connection between the chapter it opens and the general purposes of the Report. If so, if it was the writer's object to lead the lay mind to look upon his paper as pointing out methods by which, through a careful pursuit of the logical lines and the ratiocination passing through the cells or nerve-tracts of the locust's nervous system, we should in course of time be enabled to overreach and anticipate him by our superior reasoning power, in a manner comparable to that followed by a detective shadowing a forger, we can only say that it might have been omitted. Science needs no apology and the excellent plates accompanying this part of the Report alone justify the expense incurred by Government in getting them up.

We consider it unfortunate that in a chapter not likely to be perused by the lay reader at all, so much matter of a semi-popular character should have been included. It is the attempt to popularize the distinction between the brain of insects and of vertebrates (p. 224) that has led Mr. Packard to the commission of actual errors. Thus speaking of the nervous system of vertebrates, he says: "The gray matter is situated in the centre and consists largely of nerve or so-called 'ganglion cells,' while the external white matter of the brain or cord is composed of a mass of nerve fibres." This is correct only as applying to the very lowest vertebrates; in man, the mammalia and reptilia, the gray matter is more or less near the surface, in some centers altogether *cortical*, while the white matter is internal. Mr. Packard adds, as another

discrimination: "moreover the entire brain of an insect is white, as are all the ganglia."

On page 226, he says that the outer part of the brain is made up of a "slightly darker, usually pale grayish, white portion"—, where the tissue consists of small ganglion cells, it is naturally . . . . rather darker than in those regions where the tissue consists of the more loosely disposed, large ganglion cells."

So that we have a fundamental contradiction in reference to an alleged fundamental distinction, quite aside from the notorious fact that in the lowest vertebrates the nervous system is as "white" as in insects, and that the convoluted "mushroom" body or "cerebrum" of the ant contains sharply demarcated gray and white substances.

The chapter is accompanied, as stated, by plates of great value, most of these being fac similes of sections prepared by Mr. Norman J. Mason. On the whole, nothing new is added to our knowledge of the adult insectean brain in general, or the locust's in particular, that has not been carefully reported by Floegel, Newton and Michels. But through the great patience and skill of Mr. Mason, Professor Packard has been enabled to study sections from the embryo brain, a subject not yet worked up, owing to the difficulty of preparing the specimens. The most important results obtained is that the nerve-fibres develop from an originally finely granular substance, thus confirming the observations of Schmidt and Hensen for the mammalian embryo.

In view of the loudly trumpeted theory recently revived by Dr. J. J. Mason, after having repeatedly received the *coup de grace* at the hands of Stieda, Meynert and others, that large cells are motor, it is interesting to note that those of the optic ganglion in the locust are among the largest cells in its nervous system. R. C. S.

CORRESPONDENCE.

The Editor does not hold himself responsible for opinions expressed by his correspondents. No notice is taken of anonymous communications.]

To the Editor of "SCIENCE."

Limax maximas L. A specimen of this slug was brought me May 16. It came through a faucet connected with the water works. Being an introduced species and not frequently found, this fact may be of interest.

Polygala pancifolia, wild. Specimens with pure white flowers have been sent from Lunenburg, Mass., two years in succession. J. H. PILLSBURY.

SPRINGFIELD, *May* 27, 1881.

SPECTRUM ANALYSIS.

At a meeting of the Royal Astronomical Society held on the 13th of May, Mr. Norman Lockyer asked permission to offer the following address. He said:

"The chemical constitution of the heavenly bodies is one that demands some attention from astronomers. Twenty years ago the observations of Kirchoff and Stokes enabled us to get some glimpses into the chemical constitution of the sun. Kirchoff's view was that substances with which we are acquainted exist in the atmosphere of the sun, and that their presence was demonstrated by an exact matching both with respect to wave-length and intensity of the lines of certain chemical elements. Before his time Frauenhofer had noted the coincidence of the bright yellow line of sodium with the D line in the solar spectrum, but Kirchoff showed that also in the case of iron, magnesium, cobalt and several other substances there were coincidences between lines, which went to show that what was true with respect to sodium was true with respect to these other bodies. Nine years ago, we had not merely the opportunity of comparing these bright lines in the spectrum of the sun's atmosphere, as revealed to Frauenhofer, but we had the opportunity of studying the spectra obtained from very small portions of the sun's atmosphere, in regions where we should expect an exceedingly high temperature—namely, in the regions of spots and in the regions of prominences. When we began to examine these spectra, we found that the lines were thickened, and the question appeared much less clear than it did before. Of 460 iron lines recorded by Kirchoff, only three were observed in the prominences, and these were not the lines that were seen thickened in spots; so that a great many fresh questions were raised, and the idea of the decomposition of the iron by the high temperature was forced upon us. I wish to bring before you to night the results of some purely astronomical inquiries, lately undertaken by the Solar Physics Committee with respect to the behavior of the lines in the spectra of spots and prominences. We had before us the admirable work undertaken by Prof. Young in 1872, on the spectra of the prominences; but his observations only lasted for a month, and we felt that we wanted more facts, so what we have been doing at Kensington during the last two and a half years, has been to obtain and tabulate the spectra of a hundred sunspots, and these we have compared with the Italian observations of prominence lines. It was impossible to note and map down the behavior of all the lines in the spot spectra. The Committee, therefore, attempted something which was more modest, and contented themselves with observing twelve lines in the most easily visible part of the spectrum, between F and D (pinned to the blackboard was a diagram with the spectra observed placed one beneath the other, at the top were the iron lines of the Frauenhofer spectrum stated by Angstrom to be coincident with the bright lines of iron). The first point which strikes one on examining this diagram is the enormous number of iron lines, both in the solar spectrum and in the iron spectrum, as mapped by Angstrom, who used an electric arc of thirty or more Bunsen cells. They remind one of a great piano, only a few notes of which are played over and over again in the spot spectra, but always producing a different tune. If you examine the lines individually, you will find that every line has been seen with every other line. One is struck by the marvellous individuality, so to speak, of each. The lines do not go in battalions, or companies, or corporal's files, but in single units. The great importance of obtaining these observations is not so much for the observations themselves, as for the comparison they enable us to make with the observations of the lines in prominences, because the prominences are hotter than the spots. The spots are caused by down-currents where the solar atmosphere is brought down from cooler regions. They are opposed to prominences, which are ejections of heated matter from the interior of the sun. Here (pointing to the diagram) we have arranged the observations of prominences by Tacchini since 1872. What is the result? First of all, you will note a very great simplification; the brightest part of the sun has given the fewest lines. Next, there is not a single line common to the two series. In passing from the iron lines in the spots to the iron lines in the flames we pass from one spectrum to another, and the two spectra are as distinct from one another as the spectrum of magnesium is distinct from the spectrum of chlorine, or any other substance you please. These phenomena are the last we should expect. We can understand that a difference in the quantity of iron vapor present, might make a certain difference in the spectrum; but we are driven to something quite independent of any change corresponding to quantity. We see that as the temperature is increased the simplicity of the spectrum is increased; just as a chemist finds with regard to the substances which he has under his control, the function of temperature is to simplify. Why, then, if this is the result of working with increased temperature here, should not the simplification be due to the breaking

up of the iron into simpler constituents? Mr. Lockyer went on to state that the probability that the elements are so broken up by the intense heat of the lower regions of the solar atmosphere is increased by finding that many of the lines seen in the lower regions are common to more than one element. He did not believe that the bright lines seen at the beginning and end of totality which are frequently spoken of as belonging to the reversing layer correspond to the dark lines of the Frauenhofer spectrum. In witnessing another total eclipse he should concentrate his attention on two of the basic iron lines, and note their behavior at the instant of totality.

Mr. Ranyard said: It is some years since we have seen Mr. Lockyer at a meeting of the Society. I am glad to see him here again, not only for the sake of the very eloquent lecture which he has given us, but also because of the influence which a Society like this is likely to have on those who read papers before it. It gives an opportunity of criticising theories and of asking questions, which is no doubt beneficial to the person who brings the theories forward. Mr. Lockyer has referred to a theory, which he has very widely discussed, with regard to the non-elementary nature of the elements, and the evidence to be derived from solar observations, I understood him to say that he would expect a greater heat to give us a less complex spectrum.

Mr. Lockyer: I never said anything of the kind.

Mr. Ranyard; I was about to say that the reverse appears to be the case. I hope that Mr. Lockyer will afterwards take the opportunity of explaining what he means. The spectrum of the photosphere is very complicated as compared with the spectrum of sunspots and prominences. If any fact needs dwelling upon with respect to the sun, it is the number of lines which cannot be matched with terrestrial elements, and the complication of the spectrum increases as you proceed downwards to the sun's limb; that is, as you proceed from cooler to warmer regions. In the region of the Corona, very few lines have been observed; that may be, it is true, because of their faintness; but with the exception of the hydrogen lines, the lines seen in the spectrum of the Corona, which, of course, is much cooler than the region of the chromosphere, do not correspond to known lines of any terrestrial element. There is, of course, an enormous field for study here; but the fact which I want to point out, is that you do not get a simplified spectrum in the sun with greater heat, and if the facts which Mr. Lockyer has referred to with regard to the common lines in the spectra of different elements are to be relied upon, it will not follow that the common lines correspond to the similar parts of the two elements, and that the other lines correspond to mere overtones, given out with greater heat. But I should like to ask Mr. Lockyer whether he has taken note of the observations of Professor Young, who has examined these lines common to two or more elements in the solar spectrum with great dispersion, and has found that they nearly all break up into double lines or groups of lines. I think out of fifty-seven lines all but four were shown to be thus broken up, and there was some doubt about these four.

Mr. Christie said: Similar observations to those which Mr. Lockyer has described with regard to the spectra of Sunspots have been made at Greenwich, and without adopting his theory, I may say that our observations agree with those which have been made by Mr. Lockyer. We have not confined our attention merely to the iron-lines which are thickened in the spot spectrum. But we perfectly confirm what Mr. Lockyer says, namely that in the spectrum of one spot there is one group of iron-lines thickened, while in the spectrum of another spot, there will be an altogether different group affected.

TERRESTRIAL MAGNETISM.—The French Government are about to establish an observatory for terrestrial magnetism at Cape Horn.

A NEW DISCOVERY IN PHOTOGRAPHY.

At the last meeting of the Photographic Society of Great Britain, Mr. L. Warnerke described the discovery he has recently patented. The discovery he said consisted in the fact that a gelatine plate submitted to pyrogallic acid became insoluble in those parts acted upon by light, exactly in the same way as gelatine was acted upon by chromic salts, the insolubility being in propoition to the amount of light and the thickness of the gelatine. This property he proposed to utilize in various ways. The drawback in the ordinary gelatine process was that unless the exposure were very accurately timed there was considerable danger of over-exposure, and, as intensification was very difficult, pictures by the gelatine process were often interior to those by collodion. By the new process he was, however, able not only to intensify, but also to overcome the drawbacks arising from over-exposure. The latter he effected by using the emulsion on paper. He had found that no matter how much the paper was over-exposed the picture—provided the developer was restrained sufficiently—was not injured, while in the case of the emulsion on glass there was not only halation of the image, but a reversal also. The transfer of the image from paper on to the glass was a very easy matter. The paper was immersed in water and placed in contact with a glass plate. The superfluous moisture was removed by a squeegee, and the paper could then be stripped off, leaving the tissue on the glass. Hot water was then applied, which dissolved all the gelatine not acted on by light, together with the free bromide or soluble salts, and the image was left upon the glass in relief. Intensification he effected by mixing with the emulsion a coloring non-actinic matter, which was not affected by silver. Aniline colors he had found answered the purpose, and in that way special emulsion for special purposes could be prepared. That method of preparation he thought would be especially suitable for magic-lantern slides. He claimed for his discovery that by it relief could be obtained far more easily than by the ordinary bichromatised gelatine, and therefore it was especially suitable for the Woodburytype process. By mixing emery-powder with the emulsion it was rendered fit for engraving purposes, and by a combination with vitrified colors the image could be burnt in and so was adapted for enamels. In the ordinary methods of producing enamels from carbonised gelatine the latter, from the difficulty of burning it without the formation of bubbles, was a great source of trouble. By using a suitable emulsion, however, so little gelatine might be employed that this drawback was overcome. The process could also be adapted for collotype printing. In the course of his remarks, Mr. Warnerke demonstrated the removal of a gelatine picture produced by his method from paper on to glass, and showed that the mere immersion and washing in hot water fixed the picture by the dissolving of the gelatine unacted upon by light, which thus carried away the free bromide of silver. In conclusion, he stated that the sensitive paper could be used in the camera in lengths wound on rollers, and exhibited a camera which he had made for the purpose.

Captain Abney, after some remarks in reference to halation and reversal of the image, remarked that in the production of enamels by Mr. Warnerke's process there was some danger of the silver producing the well-known yellow colour which spoilt so many vitrified photographs. The discovery made by Mr. Warnerke was a most importan one, and in regard to Woodburytype, really opened up quite a new era. Mr. W. S. Bird endorsed Captain Abney's remarks as to the value of the process. To be able to produce gelatine negatives without the fear of the yellow stain was a great boon, and the only point was whether photographers would take the trouble and risk in the necessary transfers. As to its adaptability to Woodburytype, there could not be the slightest doubt. The great difficulty was to obtain the necessary relief, and he knew of a company which had recently gone to a great expense to fit up the necessary machinery, when Mr. Warnerke was able to give them what they wanted at a merely nominal cost.

Mr. T. Sebastion Davis also referred to the importance of the discovery, and suggested that by the use of the emulsion on paper a landscape might be photographed in which the clouds and the foreground might be rendered with equal truth, instead, as was too often the case, of the sky

being over-exposed. Mr. T. Bolas inquired whether Mr. Warnerke had tried adding bichromate of potash to his emulsion. The addition of bromide of silver in the case of a carbon print was supposed to increase its sensitiveness, but whether it did so he could not say. Mr. Warnerke in the course of his reply, said he had not found the yellow colour spoken of by Captain Abney, in the enamels which he had made. It was possible to eliminate all the silver by the use of ferric salts. With regard to Mr. Davis's suggestion, he was afraid he must throw cold water upon it, for he did not think it could be realized unless he used a developer for the clouds different from that used for the foreground. He had not tried bichromate of potash as mentioned by Mr. Bolas.

ESTIMATION OF FAT IN MILK.

The plan I adopt is as follows:—10 grms. of milk are evaporated in a platinum boat (of suitable construction), to near dryness (to complete dryness if you wish to determine the total solids) in the water-bath; the boat is now inserted into the extraction tube (which is plugged with a little cotton-wool and contains a stopper in the narrow part of the tube), and then connected to an upright Liebig's condenser. A small tarred flask is now fixed on to the end of the extraction tube (50 to 100 c. c. capacity) containing ether. The ether is evaporated by means of hot water, and when sufficiently condensed in the tube above, so as to completely cover the platinum boat, the stopper of the extraction tube is turned and the ether allowed to remain for about six hours or all night if convenient. All that now remains to be done is to cautiously open the stopper and allow the ether and oil to flow into the tarred flask; boil the ether repeatedly until extraction is complete. Disconnect the flask, evaporate the ether dry, and weigh the oil. The platinum boat may also be taken from the extraction tube, dried in water-bath, and weighed, which will give the solids not fat, then ignited and weighed, and we have the ash. If there is any doubt in the mind of the operator that the ether has not been able to penetrate the residue, after there have been several extractions made, the boat may be withdrawn from the extraction tube, the residue detached from its sides by means of a small platinum spatula, and the whole again returned to the extraction tube, and the operation of extraction repeated. When the extraction has been conducted as described, there is no fear of any fat being left undissolved in the residue. The following duplicate analyses are the results I have just obtained from a sample of milk I have reason to believe is genuine or unadulterated. The amount of milk operated upon was 10 grms. Specific gravity, 1027·3.

Total solids	10.2440	10.2448
Fat	1.9940	2.0001
Solids not fat	8.2500	8.2447
Ash	0.6940	0.6960

WILLIAM JOHNSON, F.I.C., F.C.S., &c.

THE ELECTRIC RAILWAY.

One of the novelties at the Crystal Palace, London, on Easter Monday, was the opening of an electrical railway, constructed by the Société Anonyme d'Electricité of Brussels, on the Siemens system. On the upper terrace of the Palace grounds, overlooking the charming scenery of Sydenham, a miniature circular line of railway, consisting of three lines of metals, has been laid down, surrounding one of the ornamental ponds, and a small wooden hut erected beside it as a passenger station. On this railway, which is about 300 metres in length, and has a gauge of about 50 centimetres, or 19 inches, between the outer rails, stands the electrical locomotive. Its length is about four feet; its breadth about a metre; its height about as much, and its weight some three-quarters of a ton. It is, in fact, a Siemens dynamo-electric machine, neatly boxed in, and mounted on a truck with four metal wheels, and provided with a break and alarm bell for its control by the man in charge. A stationary engine of about eight horse-power nominal, in a shed about thirty yards from the railway line, drives a stationary dynamo-electric machine, from which the electro-motive current is primarily obtained. Two wires are connected with this fixed dynamo-machine. By one of them the current flowing out is conveyed to the mid-rail of the railway, to which it is attached by an iron plate bolted on. The second or return wire is attached to the exterior rail of the railway. The mid-rail is supported upon wood blocks, and is thus in a certain degree insulated. Beneath the electrical locomotive a brush of iron wires sweeps the mid-rail, and the electrical current is thus taken up into the locomotive, where it passes through the mounted Siemens machine within it, the large bobbin of which is thereby caused to revolve, and the current passing away by the wheels of the truck to the exterior rails of the road, is conveyed back to the stationary dynamo-machine. As the current thus circulates, and the bobbin of the mounted machine revolves, it drives the four wheels of the truck as the locomotive moves on, hauling after it a load of nearly three tons with ease at the speed we have named.

NOTES.

INTERNAL DISCHARGES OF ELECTRIC CONDENSERS.—B. Villari.—The author's conclusions are that the heat evolved by the internal discharge may be neglected in case of feeble discharges; beyond certain limits it manifests itself and increases very rapidly with the discharges themselves; thus the first means to augment this internal heat is to make use of jars charged to a very high potential. The internal discharge is sensibly augmented if the exterior spark is produced between two small balls of 20 to 30 mm. in diameter; it decreases, on the contrary, by almost one-half if the spark is taken from a point and one of the balls. The inverse is the case for the heat produced by the external exciting spark. For a given charge the internal discharge increases if the inner coating of the jar is diminished.

RESEARCHES ON THE CHANGE OF STATE IN THE NEIGHBORHOOD OF THE CRITICAL POINT OF TEMPERATURE.—L. Cailletet and P. Hautefeuille—The authors remark that near the critical point there are witnessed for very slight variations of temperature, phenomena which have led Andrews to regard the gaseous and the liquid states as distant terms of one and the same state of matter, which may pass from one to the other by a continuous series of changes. It is impossible to know what is the state of the matter which gives rise to the moving and wavey striæ which displace each other above the mercury on operating in the vicinity of the critical point. A slow decrease of pressure often shows if a tube is filled with a liquid or a gas, for in the latter case the release gives rise to a general mist and to liquid drops; but this procedure furnishes no clue to the nature of these striæ. The authors have overcome this difficulty by coloring carbonic acid with the blue oil of galbanum. They have found that these undulating striæ dissolve the oil, and are consequently produced by liquefied carbonic acid. They conclude that matter does not pass by insensible degrees from the liquid to the gaseous state.

ON THE ACTION OF THE SELENIUM RADIOPHONE.—M. E. Mercadier observes that the sounds produced in the selenium receivers which he has studied result chiefly from the luminous radiations. The rays of the spectrum act from the limit of the blue, on the indigo side, as far as the extreme red, and even a little beyond the red. The indigo, violet, and ultra-violet rays are without perceptible action in the conditions under which he has experimented. The maximum effect is always produced in the yellow portion of the spectrum. Radiophones with glass tube-receivers containing air, in contact with a smoked surface, give a different result, the action being principally thermic.—*Comptes Rendus*.

LAW RELATING TO CABLES.—*L'Electricité* says that there is some idea of appointing a commission to inquire into the state of international law relating to submarine cables. The Minister for Foreign affairs in France, M. St. Hilaire, has stated that, in case the forthcoming Congress of Electricians should arrive at any decision on the subject, he will send a circular to the various Governments suggesting the holding of an international conference.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

TRIBUNE BUILDING, NEW YORK.

P. O. BOX 3838.

SATURDAY, JUNE 18, 1881.

AT the last meeting of the "*American Chemical Society*," Professor A. R. Leeds called attention to the reported adulteration of certain articles of food, and made special reference to the adulteration of sugar and syrups, with glucose.

The result of Dr. Leeds' examination of sugar shows, that it was of excellent quality and almost free from any adulteration, and that he was enabled, after investigations, to "contradict with equal decisiveness, the notion that table syrups are largely, almost universally, adulterated with glucose syrups."

As Dr. Leeds stated that one of the objects of his paper was to correct, what he calls, sensational reports of adulteration, and to place on record his own scientific work as evidence that adulterations to a large extent do not exist, it may be prudent to test the integrity of his work, by comparing it with results achieved by another chemist, having a high reputation as an analyst, who appears to have made investigations covering the same ground, as that instituted by Professor Leeds. We allude to Professor Harvey W. Wiley, whose paper on "Glucose and grape-sugar" appears at an opportune moment. According to Professor Wiley, the manufacture of glucose is conducted on a scale which will result in eleven million bushels of corn being used for that purpose during the present year, and as a bushel of corn will produce about 30 pounds of glucose, it would appear that over three hundred million pounds of glucose will be placed on the market during the year 1881, with every indication that the quantity will be doubled in 1882.

What becomes of all this glucose? Professor Wiley states that some of it is used for brewing beer, taking the place of malt; it is also given as a food for bees; "all soft candies, waxes and taffies, and a large proportion of stick-candies and caramels are made of glucose"; but "A VERY LARGE PROPORTION OF ALL THE GLUCOSE MADE IS USED FOR THE MANUFACTURE OF TABLE SYRUPS." * * * "When these syrups are sent into the shops, they are sold to consumers under such altisonant names as Maple Drip, Bon Ton, Upper Ten, Magnolia, Extra Choice, Golden Drip, White Loaf Drip," etc., etc. * * * "Dealers tell me that these syrups, by their cheapness and excellence, have driven all others out of the market. So much is this the case that it is no longer proper to call glucose the 'coming syrup.' It is the syrup which has already come."

"Grape sugar is used chiefly for the adulteration of other sugars. When it is reduced to fine powder; it can be mixed with cane sugar in any proportion, without altering its appearance. Since the grape-sugar costs less than half the price of cane sugar, this adulteration proves immensely profitable."

We do not propose to decide upon the issue thus raised by Professors Leeds and Wiley, but as both admit to have spoken after a full investigation, it is difficult to discover how results so different were arrived at. We believe that Professor Leeds reported correctly on the samples as he found them, but if Professor Wiley is correct, the former must have been very fortunate, or, perhaps, unfortunate, in the selection of his samples.

We are in receipt of a communication, stating that glucose sugar has now an immense sale, and that in the West, nine-tenths of the syrups on the market have but 5 to 15 per cent. of cane sugar.

Possibly in first-class stores in New York City, the sugars and syrups offered for sale are genuine, but it appears folly to shut our eyes to the immense use of glucose and grape-sugar for mixing purposes.

If Professor Leeds wishes his future communications on adulteration to be read with "vivid interest," or his reports to reach what he terms, "a commanding position in the literature of adulterations," he will offer some evidence that Professor Wiley is in error, while a few facts, showing the destination of the 500 tons of glucose and grape-sugar manufactured every day, will be timely and welcome.

We find that the first cost of glucose and grape-sugar is about one cent a pound, and that it is sold direct for three to four cents a pound. The manufacture therefore of glucose is a profitable industry, and one likely to be conducted with spirit and enterprise.

Is glucose wholesome? It may be early to answer this question, as some physicians are opposed to its use, but, as an article of food, it is now generally acknowledged to be a wholesome product, and if carefully and properly made, free from any deleterious substances. We therefore fail to find any reason why this thriving industry should not be conducted openly, and the product sold on its merits, thus escaping the odium which is cast on all counterfeit substances.

THE latest number of the journal of the *Royal Microscopical Journal* is largely occupied with papers discussing the question of angular aperture; that by Mr. Frank Crisp disposes of 60 pages, and another by Professor E. Abbe occupies 30 pages.

The editor of the *American Journal of Microscopy* proposes to offer the whole of Mr. Crisp's paper in a forthcoming number; those, therefore, who are interested in the subject can read it there in its integrity; in the meantime, the résumé to be found in another part of this issue, may be found useful. We may remind our readers that this discussion has continued for the last ten years, with the prospect of a settlement of the question as remote as ever.

Probably the Counsel for Cadet Whittaker, at the recent court-martial, was not aware of the magnitude of the question when he asked Professor Piper, of Chicago, "What is Angular Aperture?" Perhaps Mr. Park Benjamin, who is said to have prompted the question, will himself answer the question.

A WRITER in "*The Journal of Science*" defends the old system of "Weights and Measures" as against the metric system. He admits that in refined scientific investigations the metric system has advantages, but he is opposed to it for purposes of daily life and retail trade. He maintains that the nomenclature and the notation of the metric system requires reorganizing, with plain, simple and short names for its various grades, to be expressed in such a manner as to banish the decimal point beyond all ordinary transactions.

It appears to us that the metric system requires little apology for its defects, when, as the writer admits, the old system is complicated, and has a total want of unity in its weights and measures. In England, a peck of potatoes, apples, etc., is 20 lbs. in Lancashire, 21 lbs. in Sheffield, 14 lbs. in Huddersfield, and 16 lbs. in Halifax. A stone of anything is in some districts 14, and in others 16 lbs. A gill in the north of England is half, but in the south only a quarter, of a pint. Almost every county has its peculiar acre, and these examples might be multiplied.

A WRITER in "*The Astronomical Register*" draws attention to an error in the "*Memoir*" of Sir William Herschell, and repeated by Professor Holden, in "*Sir William Herschell, his Life and Works*," in styling Sir William a baronet.

We find Mr. James L. McCance is correct in making the inference that Sir William Herschell was created a knight, only. His son, Sir John Frederick William, was created a baronet in 1838.

We notice that Burke's Peerage affords little information on the subject, giving no date when the great astronomer was created a knight. Professor Holden mentions the year 1816 as the date of that event.

THE UNITY OF NATURE.

By THE DUKE OF ARGYLL.

VIII.

THE ORIGIN OF RELIGION CONSIDERED IN THE LIGHT OF THE UNITY OF NATURE.

If any one were to ask what is the origin of hunger or what is the origin of thirst, the idleness of the question would be felt at once. And yet hunger and thirst have had an origin. But that origin cannot be separated from the origin of Organic Life, and the absurdity of the question lies in this—that in asking it, the possibility of making such a separation is assumed. It involves either the supposition, that there have been living creatures which had no need of food and drink, or else the supposition, that there have been living creatures which, having that need, were nevertheless destitute of any corresponding appetite. Both of these suppositions, although not in the abstract inconceivable, are so contrary to all that we know of the laws of Nature, that practically they are rejected as impossible. There always is, and there always must be, a close correspondence between the intimations of sensibility and the necessities of Life. Hunger is the witness in sensation to the law which demands for all living things a renewal of force from the assimilation of external matter. To theorize about its origin is to theorize about the origin of that law, and consequently about the origin of embodied Life. The Darwinian formula is not applicable here. Appetite cannot have arisen out of the accidents of variation. It must have been coeval with organization, of which it is a necessary part. The same principle applies to all elementary appetites and affections, whether they be the lower appetites of the body or the higher appetites of the mind. They exist because of the existence of certain facts and of certain laws to which they stand in a relation which is natural and necessary, because it is a relation which is reasonable and fitting. Really to understand how these appetites and affections arose, it would be necessary to understand how all the corresponding facts and laws came to be. But in many cases—indeed in most cases—any such understanding is impossible, because the facts and the laws to which every appetite corresponds are in their very nature ultimate. They are laws behind which, or beyond which, we cannot get. The only true explanation of the appetite lies in the simple recognition of the adjusted relations of which it forms a part; that is to say—in a recognition of the whole system of Nature as a reasonable system, and of this particular part of it as in harmony with the rest. Any attempted explanation of it which does not start with that recognition of the reasonableness of Nature must be futile. Any explanation which not only fails in this recognition, but assumes that the origin of anything can be interpreted without it, must be not only futile but erroneous.

Men have been very busy of late in speculating on the origin of Religion. In asking this question they generally make, often as it seems unconsciously, one or other of two assumptions. One is the assumption that there is no God, and that it must have taken a long time to invent Him. The other is that there is a God, but that men were born, or created, or developed, without any sense or feeling of His existence, and that the acquisition of such a sense must of necessity have been the work of time.

I do not now say that either of these assumptions is in itself inconceivable, any more than the supposition that at some former time there were creatures needing food and drink and yet having no appetites to inform them of the fact. But what I desire to point out is, first, that one or other of these assumptions is necessarily involved in most speculations on the subject, and secondly, that, to say the least, it is possible that neither of these assumptions may be true. Yet the method of inquiry to be pursued re-

specting the origin of Religion must be entirely different, according as we start from one or other of these assumptions, or as we reject them both. If we assume that there is no God, then the question how Mankind have come so widely to invent one or more of such imaginary Beings, is indeed a question well worthy of our utmost curiosity and research. But, on the other hand, if we start with the assumption that there is a God, or indeed if we assume no more than that there are Intelligences in the Universe superior to Man, and possessing some power greater than his own over the natural system in which he lives, then the method of inquiry into the origin of Religion is immensely simplified. Obviously the question how Man first came to recognize the existence of his Creator, if we suppose such a Being to exist, becomes in virtue of that supposition relegated to the same class as the question how he first came to recognize any other of the facts or truths which it concerns him most to know. Indeed from its very nature this truth is evidently one which might be more easily and more directly made known to him than many others. The existence of a Being from whom our own being has been derived involves, at least, the possibility of some communication direct or indirect. Yet the impossibility or the improbability of any such communication is another of the assumptions continually involved in current theories about the origin of Religion. But no such assumption can be reasonably made. The perceptions of the Human Mind are accessible to the intimations of external truth through many avenues of approach. In its very structure it is made to be responsive to some of these intimations by immediate apprehension. Man has that within him by which the Invisible can be seen, and the Inaudible can be heard, and the Intangible can be felt. Not as the result of any reasoning, but by the same power by which it sees and feels the postulates on which all reasoning rests, the Human Mind may from the very first have felt that it was in contact with a Mind which was the fountain of its own.

No argument can be conducted without some assumptions. But neither ought any argument to be conducted without a clear understanding what these assumptions are. Having now cleared up the assumptions which are usually made, we can proceed with greater confidence in the discussion of the great problem before us. The origin of particular systems of religious belief is, of course, a mere question of fact. A few of these systems belong to our own time; others have arisen late in the historic ages and in the full light of contemporary evidence. Some, again, are first recognized in the dawn of those ages, and their distinctive features can only be dimly traced through evidence which is scanty and obscure. Religion is the origin of all these systems of Belief, but no one of them represents the origin of Religion. None of them throw any other light on the origin of Religion than as all exhibiting the one essential element in which all Religion consists. And it would be well if men, before philosophizing on the origin of Religion, had a more accurate conception of what they mean by it. The definitions of Religion have been even worse than the definitions of Morality. Just as the attempt is made to account for morals apart from the sense of duty or of obligation in conduct, so is the attempt made to account for Religion apart from the sense of Mind or Will in Nature. The great effort seems to have been to try how the essential idea of Religion could be either most completely eliminated or else most effectually concealed. For example, a feeling of absolute dependence has been specified by Schleiermacher as the essence of Religion. Yet it is evident that a sense of absolute dependence may be urgent and oppressive without the slightest tincture of religious feeling. A man carried off in a flood, and clinging to a log of wood, may have, and must have, a painful sense of absolute dependence on the log. But no one would think of describing this sense as a feeling of Religion. A savage may have a feeling of absolute dependence on his bows and arrows, or on the implements of his chase; or disease may bring home to him a sense of his absolute dependence on the organs of his own body, which alone enable him to use his weapons with success. But it does not follow that the savage has any feeling of Religion towards his bow, or his arrow, or his net, or his fishspear, or even to his own legs and arms. Any plausibility, therefore, which may attach to the proposition which indentifies Religion with the mere sense of dependence, is due entirely to the fact that when men speak of the sense of dependence they suggest the idea of a particular kind of dependence—namely, dependence upon a Being or a Personality, and not dependence upon a thing. That is to say, that the plausibility of the definition is entirely due to an element of thought which it is specially framed to keep out of sight. A sense of absolute dependence on purely physical things does not necessarily contain any religious element whatever. But, on the other hand, a sense of dependence on Personal or Living Agencies, whether they are supposed to be supreme or only superior religions to our own, is a feeling which is essentially religious. But the element in that feeling which makes it religious is the element of belief in a Being or in Beings who havePower and Will. When we say of any man, or of any tribe of men, that they have no Religion, we mean that they have no belief in the existence of any such Being or Beings, or at least no such belief as to require any acknowledgment or any worship[1].

The practice of worship of some kind or another is so generally associated with Religion, that we do not usually think of it otherwise than as a necessary accompaniment. It is a natural accompaniment, for the simple reason that in the very act of thinking of Superhuman Beings the mind has an inevitable tendency to think of them as possessing not only an intellectual but a moral nature which has analogies with our own. It conceives of them as having dispositions and feelings as well as mere Intellect and Will. Complete indifference towards other creatures is not natural or usual in ourselves, nor can it be natural to attribute it to other Beings. In proportion therefore as we ascribe to the Superhuman Personalities, in whose existence we believe, the authorship or the rule over, or even a mere partnership in, the activities round us, in the same proportion is it natural to regard those Beings as capable of exercising some influence upon us, whether for evil or for good. This conception of them must lead to worship—that is to say, to the cherishing of some feeling and sentiment in regard to them, and to some methods of giving it expression. There is, therefore, no mystery whatever in the usual and all but universal association of worship of some kind with all conceptions of a religious nature.

It is to be remembered, however, that, as a matter of fact, the belief in the existence of a God, or more Gods than one, has come, though rarely, to be separated from the worship of them. Among speculative philosophers this separation may arise from theories about the Divine nature, which represent it as inaccessible to supplication, or as indifferent to the sentiments of men. Among savages it may arise from the evolution of decay. It may be nothing but "a sleep and a forgetting"—the result of the breaking up of ancient homes, and the consequent impossibility of continuing the practice of rites which had become inseparably associated with local usages. Among philosophers this divorce between the one essential element of Religion and the natural accompaniments of worship, is well exhibited in the Lucretian conception of the Olympian gods, as well as in the condition of mind of many men in our own day, who have not rejected the idea of a God, but who do not feel the need of addressing Him in the language either of prayer or praise. Of this same

[1]Professor Tiele's definition of Religion corresponds with that here given:—"The relation between Man and the Superhuman Powers in which he believes." ("Outlines of the History of the Ancient Religions," p. 2.)

divorce among savages we have an example in certain Australian tribes, who are said to have a theology so definite as to believe in the existence of one God, the omnipotent Creator of heaven and of earth, and yet to be absolutely destitute of any worship.[2] Both of these, however, are aberrant phenomena—conditions of mind which are anomalous, and in all probability essentially transitional. It has been shown in the preceding pages how impossible it is to regard Australian or any other savages of the present time as representing the probable condition of Primeval man. It needs no argument to prove that it is equally impossible to regard speculative philosophers of any school as representing the mind of the earliest progenitors of our race. But neither of savages nor of philosophers who believe in a God but do not pray to Him, would it be proper to say that they have no Religion. They may be on the way to having none, or they may be on the way to having more. But men who believe in the existence of any Personal or Living Agency in Nature superior to our own, are in possession of the one essential element of all Religion. This belief is almost universally associated with practices which are in the nature of worship—with sentiments of awe, or of reverence, or of fear.

It is not inconsistent with this definition to admit that sects or individuals, who have come to reject all definite theological conceptions and to deny the existence of a living God have nevertheless been able to retain feelings and sentiments which may justly claim to be called religious. In the first place, with many men of this kind. their denial of a God is not in reality a complete denial, What they deny is very often only some particular conception of the Godhead, which is involved, or which they think is involved, in the popular theology. They are repelled, perhaps, by the familiarity with which the least elevated of human passions are sometimes attributed to the Divine Being. Or they may be puzzled by the anomalies of Nature, and find it impossible to reconcile them intellectually with any definite conception of a Being who is both all-powerful and all-good. But in faltering under this difficulty, or under other difficulties of the same kind, and in denying the possibility of forming any clear or definite conception of the Godhead, they do not necessarily renounce other conceptions which, though vague and indefinite, are nevertheless sufficient to form the nucleus of a hazy atmosphere of religious feeling and emotion. Such men may or may not recognize the fact that these feelings and emotions have been inherited from ancestors whose beliefs were purely theological, and that it is in the highest degree doubtful how long these feelings can be retained as mere survivals. It is remarkable that such feelings are even now artificially propped up and supported by a system of investing abstract terms with all the elements of personality. When men who profess to have rejected the idea of a God declare, nevertheless, as Strauss has declared, that "the world is to them the workshop of the Rational and the Good," —when they explain that "that on which they feel themselves to be absolutely dependent is by no means a brute power, but that it is Order and Law, Reason and Goodness, to which they surrender themselves with loving confidence," we cannot be mistaken that the whole of this language, and the whole conceptions which underlie it, are language and conceptions appropriate to Agencies and Powers which are possessed of all the characteristics of Mind and Will. Order and Law are, indeed, in some minds associated with nothing except matter and material forces. But neither Reason nor Goodness can be thus dissociated from the idea of Personality. All other definitions which have been given of Religion will be found on analysis to borrow whatever strength they have from involving, either expressly or implicitly, this one conception. Morality, for example, becomes Religion in proportion as all duty and all obligation is regarded as resting on the sanctions of a Divine authority. In like manner, Knowledge may be identified with Religion in proportion as all knowledge is summed up and comprehended in the perfect knowledge of One who is All in All. Nor is there any real escape from this one primary and fundamental element of Religion in the attempt made by Comte to set up Man himself—Humanity—as the object of religious worship. It is the Human Mind and Will abstracted and personified that is the object of this worship. Accordingly, in the system of Comte, it is the language of Christian and even of Catholic adoration that is borrowed as the best and fullest expression of its aspirations and desires. Such an impersonation of the Human Mind and Will, considered as an aggregate of the past and of the future, and separated from the individual who is required to worship it, does contain the one element, or at least some faint outline and shadow of the one element, which has been here represented as essential to Religion—the element, namely, of some Power in Nature other than mere brute matter or mere physical force—which Power is thought of and conceived as invested with the higher attributes of the Human Personality.

Like methods of analysis are sufficient to detect the same element in other definitions of Religion, which are much more common. When, for example, it is said that "the Supernatural" or "the Infinite" are the objects of religious thought, the same fundamental conception is involved, and is more or less consciously intended. The first of these two abstract expressions, "the Supernatural," is avowedly an expression for the existence and the agency of superhuman Personalities. It is objectionable only in so far as it seems to imply that such agency is no part of "Nature." This is in one sense a mere question of definition. We may choose to look upon our own human agency as an agency which is outside of Nature. If we do so, then, of course, it is natural to think of the agency of other Beings as outside of Nature also. But, on the other hand, if we choose to understand by "Nature" the whole system of things in which we live and of which we form a part, then the belief in the agency of other Beings of greater power does not necessarily involve any belief whatever that they are outside of that system. On the contrary, the belief in such an agency may be identified with all our conceptions of what that system, as a whole, is, and especially of its order and of its intelligibility. Whilst, therefore, "the Supernatural," as commonly understood, gives a true indication of the only real objects of religious thought, it complicates that indication by coupling the idea of Living Agencies above our own with a description of them which at the best is irrelevant, and is very apt to be misleading. The question of the existence of Living Beings superior to Man, and having more or less power over him and over his destinies, is quite a separate question from the relation in which those beings may stand to what is commonly but variously understood by "Nature."

The other phrase, now often used to express the objects of religious thought and feeling, "the Infinite," is a phrase open to objection of a very different kind. It is ambiguous, not merely as "the Supernatural" is ambiguous, by reason of its involving a separate and adventitious meaning besides the meaning which is prominent and essential; but it is ambiguous by reason of not necessarily containing at all the one meaning which is essential to Religion. "The Infinite" is a pure and bare abstraction, which may or may not include the one only object of religious consciousness and thought. An Infinite Being, if that be the meaning of "the Infinite," is indeed the highest and most perfect object of Religion. But an infinite space is no object of religious feeling. An infinite number of material units is no object of religious thought. Infinite time is no object of religious thought. On the other hand, infinite power not only

[2] "Hibbert Lectures," by Max Müller, 1878, pp. 16, 17.

may be, but must be, an object of religious contemplation in proportion as it is connected with the idea of Power in a living Will. Infinite goodness must be the object of religious thought and emotion, because in its very nature this conception involves that of a Personal Being. But if all this is what is intended by "the Infinite" then it would be best to say so plainly. The only use of the phrase, as the one selected to indicate the object of Religion, is that it may be understood in a sense that is kept out of sight. And the explanations which have been given of it are generally open to the same charge of studied ambiguity. "The Infinite" has been defined as that which transcends sense and reason,—that which cannot be comprehended or completely and wholly understood, although it may be apprehended or partially conceived.[3] And no doubt, if this definition be applied, as by implication it always is applied, to the power and to the resources, or to any other feature in the character of an Infinite Being, then it becomes a fair definition of the highest conceivable object of religious thought. But, again, if it be not so applied,—if it be understood as only applying to the impossibility under which we find ourselves of grasping anything which is limitless,—of counting an infinite number of units,—of traversing, even in thought, an infinite space,—of living out an infinite time,—then "the Infinite" does not contain the one essential element which constitutes Religion.

Similar objections apply to another abstract phrase, sometimes used as a definition of the object of religious feeling, namely, "the Invisible." Mere material things, which are either too large to be wholly seen, or too small to be seen at all, can never supply the one indispensable element of Religion. In so far, therefore, as invisibility applies to them only, it suggests nothing of a religious nature. But in so far as "the Invisible" means, and is intended to apply to, living Beings who are out of sight, to Personal Agencies which either have no bodily form, or who are thought of and conceived as separate from such form—in so far, of course, "the Invisible," like "the Infinite," does cover and include the conception without which there can be no Religion.

Definitions of meaning are more or less important in all discussions; but there are many questions in which they are by no means essential, because of the facility of which we refer the abstract words we may be using to the concrete things,—to the actual phenomena to which they are applied. When, for example, we speak of the religion of Mahomet, or of the religion of Confucius, or of the religion of Buddha, we do not need to define what we mean by the word "Religion," because in all of these cases the system of doctrine and the conceptions which constitute those religions are known, or are matters of historical evidence. But when we come to discuss the origin, not of any particular system of belief, but of Religion in the abstract, some clear and intelligible definition of the word Religion becomes absolutely essential, because in that discussion we are dealing with a question which is purely speculative. It is idle to enter upon that speculative discussion unless we have some definite understanding what we are speculating about. In the case of Religion we cannot keep our understanding of the word fresh and distinct by thinking of any well-known and admitted facts respecting the beginnings of belief. There are no such facts to go upon as regards the religion of Primeval Man. Those, indeed, who accept the narrative attributed to the inspired authority of the Jewish Lawgiver have no need to speculate. In that narrative the origin of Religion is identified with the origin of Man, and the Creator is represented as having had, in some form or another, direct communication with the creature He had made. But those who do not accept that narrative, or who, without rejecting it altogether, regard it as so full of metaphor that it gives us no satisfying explanation, and who assume that Religion has had an origin subsequent to the origin of the species, have absolutely nothing to rely upon in the nature of history. There is no contemporary evidence, nor is there any tradition which can be trusted. Primeval man has kept no journal of his own first religious emotions, any more than of his own first appearance in the world. We are therefore thrown back upon pure speculation — speculation indeed, which may find in the present, and in a comparatively recent past, some data for arriving at conclusions, more or less probable, on the conditions of a time which is out of sight. But among the very first of these data, if it be not indeed the one datum without which all others are useless, is a clear conception of the element which is common to all religions as they exist now, or as they can be traced back beyond the dawn of history into the dim twilight of tradition. Of this universal element in all religions "the Infinite" is no definition at all. It is itself much more vague and indefinite in meaning than the word which it professes to explain. And this is all the more needless, seeing that the common element in all religions, such as we know them now, is one of the greatest simplicity. It is the element of a belief in superhuman Beings—in Living Agencies, other and higher than our own.

It is astonishing how much the path of investigation is cleared before us the moment we have arrived at this definition of the belief which is fundamental to all religions. That belief is simply a belief in the existence of Beings of whom our own Being is the type, although it need not be the measure or the form. By the very terms of the definition the origin of this belief is and must be in ourselves. That is to say, the disposition to believe in the existence of such Beings arises out of the felt unity of our own nature with the whole system of things in which we live and of which we are a part. It is the simplest and most natural of all conceptions that the agency of which we are most conscious in ourselves is like the Agency which works in the world around us. Even supposing this conception to be groundless, and that, as some now maintain, a more scientific investigation of natural agencies abolishes the conception of design or purpose, or of personal Will being at all concerned therein,—even supposing this, it is not the less true that the transfer of conceptions founded on our own consciousness of agency and of power within us to the agencies and powers around us, is a natural, if it be not indeed a necessary conception. That it is a natural conception is proved by the fact that it has been, and still is so widely prevalent; as well as by the fact that what is called the purely scientific conception of natural agencies is a modern conception, and one which is confessedly of difficult attainment. So difficult indeed is it to expel from the mind the conception of personality in or behind the agencies of Nature, that it may fairly be questioned whether it has ever been effectually done. Verbal devices for keeping the idea out of sight are indeed very common; but even these are not very successful. I have elsewhere pointed out[4] that those naturalists and philosophers who are most opposed to all theological explanations or conceptions of natural forces do, nevertheless, habitually, in spite of themselves, have recourse to language which derives its whole form as well as its whole intelligibility, from those elements of meaning which refer to the familiar operations of our own Mind and Will. The very phrase "Natural Selection" is one which likens the operations of Nature to the operations of a mind exercising the power of choice. The whole meaning of the phrase is to indicate how Nature attains certain ends which are like "selection." And what "selection" is we know, because it is an operation familiar to ourselves. But the personal element of Will and of purpose lies

[3] Max Müller, "Hibbert Lectures," 1878.

[4] "Reign of Law," Chaps. I. and V.

even deeper than this in the scientific theory of Evolution. When we ourselves select, we may very often choose only among things ready made to our hands. But in the theory of Evolution, Nature is not merely represented as choosing among things ready made, but as at first making the things which are to be afterwards fitted for selection. Organs are represented as growing in certain forms and shapes "in order that" they may serve certain uses, and then as being "selected" by that use in order that they may be established and prevail. The same idea runs throughout all the detailed descriptions of growth and of development by which these processes are directed to useful and serviceable results. So long as in the mere description of phenomena men find themselves compelled to have recourse to language of this sort, they have not emancipated themselves from the natural tendency of all human thought to see the elements of our own personality in the energies and in the works of Nature. But whether the attempt at such emancipation be successful or not, the very effort which it requires is a proof of the natural servitude under which we lie. And if it be indeed a natural servitude, the difficulty of getting rid of it is explained. It is hard to kick against the pricks. There is no successful rebellion against the servitudes of Nature. The suggestions which come to us from the external world, and which are of such necessity that we cannot choose but hear them, have their origin in the whole constitution and course of things. To seek for any origin of them apart from the origin of our whole intellectual nature, and apart from the relations between that nature and the facts of the universe around us, is to seek for something which does not exist. We may choose to assume that there are no Intelligences in Nature superior to our own; but the fact remains that it is a part of our mental constitution to imagine otherwise. If, on the other hand, we assume that such Intelligences do exist, then the recognition of that existence, or the impression of it, is involved in no other difficulty than is involved in the origin of any other part of the furniture of our minds. What is the origin of Reason? The perception of logical necessity is the perception of a real relation between things; and this relation between things is represented by a corresponding relation between our conceptions of them. We can give no account of the origin of that perception unless we can give an account of the origin of Man, and of the whole system to which he stands related. What, again, is the origin of Imagination? It is the mental power by which we handle the elementary conceptions derived from our mental constitution in contact and in harmony with external things, and by which we combine these conceptions in an endless variety of forms. We can give no account of the origin of such a power or of such a habit. What is the origin of Wonder? In the lower animals a lower form of it exists in the shape of Curiosity, being little more than an impulse to seek for that which may be food, or to avoid that which may be danger. But in Man it is one of the most powerful and the most fruitful of all his mental characteristics. Of its origin we can give no other account than that there exists in Man an indefinite power of knowing, in contact with an equally indefinite number of things which are to him unknown. Between these two facts the connecting link is the wish to know. And, indeed, if the system of Nature were not a reasonable system, the power of knowing might exist in Man without any wish to use it. But the system of Nature, being what it is—a system which is the very embodiment of wisdom and knowledge—such a departure from unity is impossible. That unity consists in the universal and rational correspondence of all its essential facts. There would be no such correspondence between the powers of the human mind and the ideas which they are fitted to entertain, if these powers were not incited by an appetite of inquiry. Accordingly, the desire of knowledge is as much born with Man as the desire of food. The impression that there are things around him which he does not know or understand, but which he can know and understand by effort and inquiry, is so much part of Man's nature that Man would not be Man without it. Religion is but a part of this impression—or rather it is the sum and consummation of all the intimations from which this impression is derived. Among the things of which he has an impression as existing, and respecting which he desires to know more, are above all other things, Personalities or Agencies, or Beings having powers like, but superior to his own. This is Religion. In this impression is to be found the origin of all Theologies. But of its own origin we can give no account until we know the origin of Man.

I have dwelt upon this point of definition because those who discuss the origin of Religion seem very often to be wholly unconscious of various assumptions which are necessarily involved in the very question they propound. One of these assumptions clearly is that there was a time when Man existed without any feeling or impression that any Being or Beings superior to himself existed in Nature or behind it. The assumption is that the idea of the existence of such Beings is a matter of high and difficult attainment, to be reached only after some long process of evolution and development. Whereas the truth may very well be, and probably is, that there never was a time since Man became possessed of the mental constitution which separates him from the brutes, when he was destitute of some conception of the existence of living Agencies other than his own. Instead of being a difficult conception, it may very well turn out to be, on investigation, the very simplest of all conceptions. The real difficulty may lie not in entertaining it, but in getting rid of it, or in restraining its undue immanence and power. The reason of this difficulty is obvious. Of all the intuitive faculties which are peculiar to Man, that of self-consciousness is the most prominent. In virtue of that faculty or power, without any deliberate reasoning or logical process of any formal kind, Man must have been always familiar with the idea of energies which are themselves invisible, and only to be seen in their effects. His own loves and hates, his own gratitude and revenge, his own schemes and resolves, must have been familiar to him from the first as things in themselves invisible, and yet having power to determine the most opposite and the most decisive changes for good or evil in things in themselves invisible, and yet having power to determine the most opposite and the most decisive changes for good or evil in things which are visible and material. The idea of Personality, therefore, or of the efficiency of Mind and Will, never could have been to him inseparable from the attributes of visibility. It never could have been any difficulty with him to think of living Agencies other than his own, and yet without any form, or with forms concealed from sight. There is no need therefore to hunt farther afield for the origin of this conception than Man's own consciousness of himself. There is no need of going to the winds which are invisible, or to the heavenly bodies which are intangible, or to the sky, which is immeasurable. None of these, in virtue either of mere invisibility, or of mere intangibility, or of mere immeasurableness, could have suggested the idea which is fundamental in Religion. That idea was indeed supplied to Man from Nature; but it was from his own nature in communion with the nature of all things around him. To conceive of the energies that are outside of him as like the energies that he feels within him, is simply to think of the unknown in terms of the familiar and the known. To think thus can never have been to him any matter of difficult attainment. It must have been, in the very nature of things, the earliest, the simplest, and the most necessary of all conceptions.

The conclusion, then, to which we come from this analysis of Religion is that there is no reason to believe, but on the contrary many reasons to disbelieve, that there

ever was a time when man with his existing constitution, lived in contact with the forces and in the face of energies of Nature, and yet with no impression or belief that in those energies, or behind them, there were Living Agencies other than his own. And if man, ever since he became Man, had always some such impression or belief, then he always had a Religion, and the question of its origin cannot be separated from the origin of the species.

It is a part of the Unity of Nature that the clear perception of any one truth leads almost always to the perception of some other, which follows from or is connected with the first. And so it is in this case. The same analysis which establishes a necessary connection between the self-consciousness of Man and the one fundamental element of all religious emotion and belief, establishes an equally natural connection between another part of the same self-consciousness and certain tendencies in the development of Religion which we know to have been widely prevalent. For although in the operations of our own mind and spirit, with their strong and often violent emotions, we are familiar with a powerful agency which is in itself invisible, yet it is equally true that we are familiar with that agency as always working in and through a body. It is natural, therefore, when we think of Living Agencies in Nature other than our own, to think of them as having some form, or at least as having some abode. Seeing, however, and knowing the work of those Agencies to be work exhibiting power and resources so much greater than our own, there is obviously unlimited scope for the imagination in conceiving what that form and where that abode may be. Given, therefore, these two inevitable tendencies of the human mind—the tendency to believe in the existence of Personalities other than our own, and the tendency to think of them as living in some shape and in some place—we have a natural and sufficient explanation, not only of the existence of Religion, but of the thousand forms in which it has found expression in the world. For as Man since he became Man, in respect to the existing powers and apparatus of his mind, has never been without the consciousness of self, nor without some desire of interpreting the things around him in terms of his own thoughts, so neither has he been without the power of imagination. By virtue of it he re-combines into countless new forms not only the images of sense but his own instinctive interpretations of them. Obviously we have in this faculty the prolific source of an infinite variety of conceptions, which may be pure and simple or foul and unnatural, according to the elements supplied out of the moral and intellectual character of the minds which are imagining. Obviously, too, we have in this process an unlimited field for the development of good or evil germs. The work which in the last chapter I have shown to be the inevitable work of Reason when it starts from any datum which is false, must be, in religious conceptions above all others, a work of rapid and continuous evolution. The steps of natural consequence, when they are downward here, must be downwards along the steepest gradients. It must be so because the conceptions which men have formed respecting the Supreme Agencies in Nature are of necessity conceptions which give energy to all the springs of action. They touch the deepest roots of motive. In thought they open the most copious fountains of suggestion. In conduct they affect the supreme influence of Authority, and the next most powerful of all influences, the influence of Example. Whatever may have been false or wrong, therefore, from the first in any religious conception must inevitably tend to become worse and worse with time, and with the temptation under which men have lain to follow up the steps of evil consequence to their most extreme conclusions.

Armed with the certainties which thus arise out of the very nature of the conceptions we are dealing with when we inquire into the origin of Religion, we can now approach that question by consulting the only other sources of authentic information, which are, first, the facts which Religion presents among the existing generations of men, and, secondly, such facts as can be safely gathered from the records of the past.

On one main point which has been questioned respecting existing facts, the progress of inquiry seems to have established beyond any reasonable doubt that no race of men now exists so savage and degraded as to be, or to have been when discovered, wholly destitute of any conceptions of a religious nature. It is now well understood that all the cases in which the existence of such savages has been reported, are cases which break down upon more intimate knowledge and more scientific inquiry.

Such is the conclusion arrived at by a careful modern inquirer, Professor Tiele, who says: "The statement that there are nations or tribes which possess no religion, rests either on inaccurate observations or on a confusion of ideas. No tribe or nation has yet been met with destitute of belief in any higher Beings, and travelers who asserted their existence have been afterwards refuted by facts. It is legitimate, therefore, to call Religion, in its most general sense, an universal phenomenon of humanity."[5]

Although this conclusion on a matter of fact is satisfactory, it must be remembered that, even if it had been true that some savages do exist with no conception whatever of Living Beings higher than themselves, it would be no proof whatever that such was the primeval condition of Man. The arguments adduced in a former chapter, that the most degraded savagery of the present day is or may be the result of evolution working upon highly unfavorable conditions, are arguments which deprive such facts, even if they existed, of all value in support of the assumption that the lowest savagery was the condition of the first progenitors of our race. Degradation being a process which has certainly operated, and is now operating upon some races, and to some extent, it must always remain a question how far this process may go in paralyzing the activity of our higher powers or in setting them, as it were, to sleep. It is well, however, that we have no such problem to discuss. Whether any savages exist with absolutely no religious conceptions is, after all, a question of subordinate importance; because it is certain that, if they exist at all, they are a very extreme case and a very rare exception. It is notorious that, in the case of most savages and of all barbarians, not only have they some Religion, but their Religion is one of the very worst elements in their savagery or their barbarism.

Looking now to the facts presented by the existing Religions of the world, there is one of these facts which at once arrests attention, and that is the tendency of all Religions, whether savage or civilized, to connect the Personal Agencies who are feared or worshipped with some material object. The nature of that connection may not be always—it may not be even in any case—perfectly clear and definite. The rigorous analysis of our own thoughts upon such subjects is difficult, even to the most enlightened men. To rude and savage men it is impossible. There is no mystery, therefore, in the fact that the connection which exists between various material objects and the Beings who are worshipped in them or through them, is a connection which remains generally vague in the mind of the worshipper himself. Sometimes the material object is an embodiment; sometimes it is a symbol; often it may be only an abode. Nor is it wonderful that there should be a like variety in the particular objects which have come to be so regarded. Sometimes they are such material objects as the heavenly bodies. Sometimes they are natural productions of our own planet, such as particular trees, or particular animals, or particular things in themselves inanimate, such as springs, or streams, or

[5] "History of Religion," p. 6.

mountains. Sometimes they are manufactured articles, stones or blocks of wood cut into some shape which has a meaning either obvious or traditional.

The universality of this tendency to connect some material objects with religious worship, and the immense variety of modes in which this tendency has been manifested, is a fact which receives a full and adequate explanation in our natural disposition to conceive of all Personal Agencies as living in some form and in some place, or as having some other special connection with particular things in Nature. Nor is it difficult to understand how the embodiments, or the symbols, or the abodes, which may be imagined and devised by men, will vary according as their mental condition has been developed in a good or in a wrong direction. And as these imaginings and devices are never, as we see them now among savages, the work of any one generation of men, but are the accumulated inheritance of many generations, all existing systems of worship among them must be regarded as presumably very wide departures from the conceptions which were primeval. And this presumption gains additional force when we observe the distinction which exists between the fundamental conceptions of religious belief and the forms of worship which have come to be the expression and embodiment of these. In the Religion of the highest and best races, in Christianity itself, we know the wide difference which obtains between the theology of the Church and the popular superstitions which have been developed under it. These superstitions may be, and often are, of the grossest kind. They may be indeed, and in many cases are known to be, vestiges of Pagan worship which have survived all religious revolutions and reforms; but in other cases they are the natural and legitimate development of some erroneous belief accepted as part of the Christian creed. Here, as elsewhere, Reason working on false data has been, as under such conditions it must always be, the great agent in degradation and decay.

METEOROLOGICAL ELECTRICITY.

Ciel et Terre gives a description of a cyclone which passed over Japan on the night of the 3d or 4th of October, 1880. At Tokio a rapidity of 45 metres per second has been observed, but this had only a rapidity of 10 metres; its diameter was not very considerable, 240 kilometres. The fall of the barometer, though rapid, was far from being as prompt as that occurring eight days before on the coasts of the Island of Formosa, where a depression of 73 millimetres in 4 hours, or 18 millimetres per hour, was observed. These indicate that the old theory of whirlwinds is perfectly useless to account for meteorological phenomena.

THE APERTURE OF MICROSCOPE-OBJECTIVES.

The last number of the *Journal* of the Royal Microscopical Society is largely occupied with a discussion of this question by Prof. E. Abbe, of Jena, and Mr. Frank Crisp, one of the secretaries of the Society.

The subject appears to have been again brought up by a paper by Mr. G. Shadbolt (President of the Society in 1856), who claimed to have "demonstrated beyond dispute that no objective could have an aperture of any kind in excess of 180° angular in air." The grounds on which Mr. Shadbolt rested his demonstration are disposed of in detail in the papers now published; but with this aspect of the matter we do not propose to deal, confining ourselves to the more general consideration of the subject, apart from any controversial matter.

The proper definition of the aperture of a microscope-objective was, for a long time, as is well known, a very vexed one among microscopists. The astronomer has always a ready definition for the telescope, the aperture of which was simply estimated by the absolute diameter of the object-glass. No such absolute measure is, however, possible in the case of the microscope-objective, as the lenses of which it is composed vary in diameter within considerable limits, and the larger lens is by no means the larger aperture, as is readily seen by the comparison of the large lenses of the low powers with the small lenses of the high powers, which yet much exceed the former in aperture.

In consequence of this difficulty, the angle of the pencil, as it emanates from the object, and prior to its transmission through the objective to the image, came to be very generally considered as the proper measure of the aperture of the objective. This was at a time when dry or air objectives were generally known, immersion objectives not having been brought into ordinary use.

But even with air objectives the angle of the radiant pencil did not afford a true comparison, which could only be made by the *sines* of the angles; but when immersion objectives were originated—that is, objectives in which water or oil replaced the air in front of the objective—the use of the angles became very misleading, for now three angles might all have the same number of degrees and yet denote very different values, according as they are in air, water, or oil.

It therefore became necessary to find a substitute for the angles in the comparison of apertures; for although it was no doubt possible to bear in mind that 82° in air was less aperture than 82° in water, and the latter less than 82° in oil, yet the use of the same figures inevitably tended to produce confusion in the minds of microscopists—so much so that it was stoutly maintained by one party that the apertures in the three cases we have referred to were identical because the angles were the same.

A solution of the difficulty was discovered by Professor Abbe, who pointed out that the true definition of aperture (in its legitimate meaning of "opening") was obtained when we compared the diameter of the pencil emerging from the objective with the focal length of the objective.

It will be desirable to explain somewhat more in detail how this conclusion is arrived at—as given in Prof. Abbe's paper.

Taking in the first case a *single*-lens microscope, the number of rays admitted within one meridional plane of the lens evidently increases as the diameter of the lens (all other circumstances remaining the same), for in the microscope we have at the back of the lens the same circumstances as are in front in the case of the telescope. The larger or smaller number of emergent rays will, therefore, be properly measured by the clear diameter; and as no rays can *emerge* that have not first been *admitted*, this must also give the measure of the admitted rays.

Suppose now that the focal lengths of the lenses compared are not the same,—what then is the proper measure of the rays admitted?

If the two lenses have equal openings but different focal lengths, they transmit the same number of rays to equal areas of an image at a definite distance, because they would admit the same number if an object were substituted for the image—that is, if the lens were used as a telescope-objective. But as the focal lengths are different the amplification of the images is different also, and equal areas of these images correspond to different areas of the object from which the rays are collected. Therefore, the higher-power lens, with the same opening as the lower power, will admit a *greater* number of rays in all from the same object because it admits the *same* number as the latter from a *smaller* portion of the object. Thus if the focal lengths of the two lenses are as 2:1, and the first amplifies N diameters, the second will amplify 2 N with the same distance of the image, so that the rays which are collected *to* a given field of 1 mm. diameter of

the image are admitted *from* a field of $\frac{1}{N}$ mm. in the first case and of $\frac{1}{2N}$ mm. in the second. Inasmuch as the "opening" of the objective is estimated by the diameter (and not by the area) the higher-power lens admits *twice* as many rays as the lower power, because it admits the *same* number from a field of *half* the diameter, and in general the admission of rays with the same opening, but different powers, must be in the inverse ratio of the focal lengths.

In the case of the single lens, therefore, its aperture must be determined by *the ratio between the clear opening and the focal length,* in order to define the same thing as is denoted in the telescope by the *absolute* opening.

Dealing with a *compound objective,* the same considerations obviously apply, substituting, however, for the clear opening of the single lens, the diameter of the pencil at its emergence from the black lens of the objective —that is, its clear effective diameter.

All equally holds good, whether the medium in which the objective is placed is the same in the case of the two objectives or different, as an alteration of the medium makes no difference in the power.

Thus we arrive at the general proposition for all kinds of objectives. 1st. When the power is the same, the admission of rays varies with the diameter of the pencil at its emergence. 2nd. When the powers are different the *same admission* requires *different openings* in the proportion of the focal lengths, or, conversely, with the *same opening the admission is in inverse proportion* to the focal length—that is, the objective which has the wider pencil relatively to its focal length has the larger aperture.

Thus we see that, just as in the telescope, the absolute diameter of the object-glass defines the aperture, so in the microscope, the ratio between the utilized diameter of the back lens and the focal length of the objective defines its aperture.

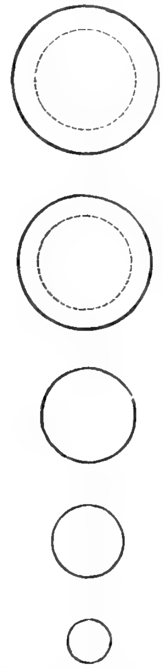
This definition is clearly a definition of aperture in its primary and only legitimate meaning as "opening"—that is, the capacity of the objective for admitting rays from the object and transmitting them to the image; and it at once solves the difficulty which has always been involved in the consideration of the apertures of immersion objectives.

So long as the angles were taken as the proper expression of aperture, it was difficult for those who were not well versed in optical matters to avoid regarding an angle of 180° in air as the maximum aperture that any objective could attain. Hence water-immersion objectives of 96° and oil-immersion objectives of 82° were looked upon as being of much *less* aperture than a dry objective of 180°, whilst, in fact, they are all *equal*—that is, they all transmit the same rays from the object to the image. Therefore, 180° in water and 180° in oil are unequal, and both are much larger apertures than the 180° which is the maximum that the air objective can transmit.

If we compare a series of dry and oil-immersion objectives, and, commencing with very small air-angles, progress up to 180° air-angle, then taking an oil-immersion of 82° and progressing again to 180° oil-angle, the ratio of opening to power progresses continually also, and attains its maximum, not in the case of the air-angle of 180° (when it is exactly equivalent to the oil-angle of 82°), but is greatest at the oil-angle of 180°.

If we assume the objectives to have the same power throughout, we get rid of one of the factors of the ratio, and we have only to compare the diameters of the emergent beams, and can represent their relations by diagrams. Our figure (which is taken from Mr. Crisp's paper) illustrates five cases of different apertures of ¼ in. objectives—viz., those of dry objectives of 60°, 97° and 180° air-angle, a water-immersion of 180° water-angle, and an oil-immersion of 180° oil-angle. The inner dotted circles in the two latter cases are of the same size as that corresponding to the 180° air angle.*

RELATIVE DIAMETERS OF THE (UTILIZED) BACK-LENSES OF VARIOUS DRY AND IMMERSION OBJECTIVES OF THE SAME POWER (¼) FROM AN AIR-ANGLE OF 60° TO AN OIL-ANGLE OF 180°.



Numerical Aperture 1.52 = 180° oil-angle.

Numerical Aperture 1.33 = 180° water-angle.

Numerical Aperture 1.00 = 180° air-angle. = 96° water-angle. = 82° oil-angle.

Numerical Aperture .75 = 97° air-angle.

Numerical Aperture .50 = 60° air-angle.

A dry objective of the full maximum air-angle of 180° is only able (whether the first surface is plane or concave) to utilise a diameter of back lens equal to twice the focal length, while an immersion lens of even only 100° (in glass) requires and utilises a *larger* diameter, *i. e.,* it is able to transmit more rays from the object to the image than *any* dry objective is capable of transmitting. Whenever the angle of an immersion lens exceeds twice the critical angle for the immersion-fluid, *i. e.,* 96° for water or 82° for oil, its aperture is in excess of that of a dry objective of 180°.

Having settled the principle, it was still necessary, however, to find a proper notation for comparing apertures. The astronomer can compare the apertures of his various telescopes by simply expressing them in inches; but this is obviously not available to the microscopist, who has to deal with the *ratio* of two varying quantities.

Prof. Abbe here again conferred a boon upon microscopists by his discovery (in 1873, independently confirmed by Prof. Helmholtz shortly afterwards) that a general relation existed between the pencil admitted into the front of the objective and that emerging from the back of the objective, so that the ratio of the semi-diameter of the emergent pencil to the focal length of the objective could be expressed by the sine of half the angle of aperture (u) multiplied by the refractive index of the medium (n) in front of the objective, or n sin. u (n being 1.0 for air, 1.33 for water, and 1.5 for oil or balsam).

When, then, the values in any given cases of the expression n sin. u (which is known as the "numerical aperture") has been ascertained, the objectives are instantly compared as regards their aperture, and, more-

* The explanation of the mistaken supposition that the emergent beam is wider in the case of the immersion objectives because the immersion-fluid abolishes the refractive action of the first plane surface of the objective (which, in air, reduces all pencils to 80° within the glass), belongs rather to the controversial branch of the matter. It is, however, fully dealt with in the papers referred to.

over, as $180°$ in air is equal to 1.0 (since $n = 1.0$, and the sine of half $180°$ or $90° = 1.0$), we see with equal readiness whether the aperture of the objective is smaller or larger than that corresponding to $180°$ in air.

Thus, suppose we desire to compare the relative apertures of three objectives, one a dry objective, the second a water-immersion, and the third an oil-immersion. These would be compared on the angular aperture view as, say, $74°$ air-angle, and $118°$ balsam-angle; so that a calculation must be worked out to arrive at a due appreciation of the actual relation between them. Applying, however, "numerical" aperture, which gives .60 for the dry objective, .90 for the water-immersion, and 1.30 for the oil-immersion, their relative apertures are immediately appreciated, and it is seen, for instance, that the aperture of the water-immersion is somewhat less than that of a dry objective of $180°$, and that the aperture of the oil-immersion exceeds that of the latter by 30 .

When these considerations have been appreciated, the advantage possessed by immersion in comparison with dry objectives is no longer obscured. Instead of this advantage consisting merely in increased working distance or absence of correction-collar, it is seen that a wide-angled immersion objective has a larger aperture than a dry objective of the maximum angle of $180°$; so that for any of the purposes for which aperture is desired, an immersion must necessarily be preferred to a dry objective.

The task of making an abstract of these papers was not a light one and we are indebted to the *English Mechanics* for the above résumé.

BOOKS RECEIVED.

Discovery of the Preglacial Outlet of the Basin of Lake Erie into that of Lake Ontario; with notes on the Origin of our Lower Great Lakes. By Prof. J. W. Spencer, B. A. Sc., Ph. D., F. G. S., Kings College, Windsor, N. S. 1881.

As one new branch of knowledge is raised to a science, there still seems to be some other rising to importance. For a long time the explanation of the Physical Features of America has been handed over to the rival Glacier and Iceberg theories, and though much good work has resulted, yet an almost unlimited amount of nonsense has been written, especially by the extreme or ultra-glacial school. During all these years comparatively little attention has been given to the subject of the river geology, more than that many buried channels have been recorded with but few attempts at the reduction of the abstract facts to a branch of Science. There has, however, been a very great difficulty, owing to the Preglacial valleys often being entirely obscured, or, if apparent, an absence of the knowledge of their depths has prevented generalization. In most of the cases recorded, the buried channels have not had courses greatly differing from those of modern times. It has been known for some time that the waters of most of the great lakes had southern outlets when at higher levels, and even to-day the drainage of Chicago passes to the Mississippi. It has been frequently suggested that Lake Ontario emptied by the Mohawk into the Hudson. This, however, was not the case. We are then compelled to place General G. K. Warren as the father of Fluviatile Geology, for he discovered that the Red River of the North (with Lake Winnipeg, the Saskatchewan, and other great rivers of the North West territories of Canada, as tributaries) discharged by the Minnesota river into the Mississippi, and thus produced a river to which no modern water is comparable. On further investigation Gen. Warren's views are found to require some modification, yet this does not detract from the position which may be fairly assigned to him. Dr. Newbury's observations in Ohio have also thrown much additional light on the subject, but a much more important work has been accomplished by Mr. J. F. Carll, of Pennsylvania, when from a careful study of the levels and borings for oil in that State, he discovered that the Upper Alleghany and several other rivers now flowing into the Ohio, formerly emptied into Lake Erie (or its basin).

But the most important contribution on the subject of Fluviatile Geology that has been made is the recent paper of the above title, by Professor Spencer, now of Kings College, Nova Scotia, but formerly residing in the lake region, in the Province of Ontario. The paper of the above title was read before the American Philosophical Society, of Philadelphia, and its publication will be found in the forthcoming proceedings of that Society. It is also being reprinted as an appendix to Report Q 4 of the Pennsylvania Survey, as shown by the maps which accompany the author's edition, of which we have just received a copy. The following is a synopsis of the principal points of the paper:

The Niagara escarpment bends abruptly at the western end of Lake Ontario, and has a height of about 500 feet above the lake. Through this limestone ridge the Dundas valley extends, and enters the extreme western end of the lake. At the narrowest portion of the valley the width is upwards of two miles, and the margins are those of the walls of a perfect *cañon*, 500 feet deep. But by boring near one of its margins, the buried channel is found to reach 227 feet below the surface of Lake Ontario, making a total depth of 743 feet, but with a computed depth in the central part of its course of not less than 1000 feet. The author first discovered that the ancient upper portion of the Grand River left its modern course south of Galt, and although a portion of the old bed is entirely obscured, yet by pursuing the course of the deep wells the ancient route can be traced through the drift to the western end of the Dundas *cañon* and Lake Ontario. In following up this subject Dr. Spencer discovered that the lower portion of the Grand River was formerly an outlet of the Erie basin, which discharged by a course from a point southward of Cayuga (Province of Ontario), and flowed to the westward of this town and entered the present valley, which is two miles wide and eighty feet deep, but underlaid deeply with drift. Westward of Seneca the ancient river left its modern course and passed into the Dundas valley. All these observations are elaborately worked out by levels, deep well borings, and deep ravines, with the one well in this course indicating a depth of 1000 feet of drift in the ancient valley, measuring from the limestone floor of the county.

The outlet of Lake Erie is directly opposite to that of the ancient Alleghany River.

Again, Dr. Spencer has made a study of the soundings of the lakes, and has discovered a long submerged escarpment extending along the southern side of Lake Ontario to near Oswego, at the foot of which the Ancient River from the Dundas Valley ran. The author has shown that an ancient, broad channel, extended from Lake Huron and entered Lake Erie between Port Stanley and Vienna, in the Canadian Province of Ontario. This channel has a marginal depth of 200 feet below Lake Erie, but with a probable depth sufficient to drain Lake Huron.

With regard to Lake Superior, Prof. Spencer shows that it formerly emptied into the northern end of Lake Michigan, and formed a river channel now represented by deep pot-holes. He brings forward some of the evidence showing that Lake Michigan emptied or was completely drained by the tributaries of the Mississippi, and that this lake was probably disconnected from Lake Huron. At the same time, he shows that Lake Superior (when it was at no higher level than at present) did not empty by the Green Bay and valley of the Fox and Wisconsin Rivers.

The author denies the hypothesis of the glacial origin of the Great Lakes, and brings forward strong evidence in support of his views. He correlates with his work and maps the buried channels discovered in Pennsylvania and

Ohio, the whole constituting the broadest study on the "Great River Age" that has been made. He considers the great lakes as largely valleys of subaërial erosion, traversed by the Grand River which he has worked out. The Ancient buried course of the Niagara, the author considers as interglacial, being formed and closed subsequent to the closing of the Dundas Valley. Of course, all this presupposes the action to have been going on when the continent was six hundred feet higher, and from the pot-holes in the New York Harbor, we know it to have had an altitude of at least 900 above the present elevation. To perfect the work there remains the discovery of the outlet of Lake Ontario, which was not by the Mohawk, as in its valley near Little Falls, it passes over hard rock. Yet Prof. Spencer insinuates, in this paper, that he is on the track of this discovery also, and that the study will be pursued during the coming summer. We wish the author every success, and if this ancient outlet be discovered, certainly he will have added much to his already most important discovery, and will fairly be considered as one of the founders of this new scientific development.

It must be further stated that the author does not consider all the ancient buried rivers now running southward, but formerly flowing northward, as having in any way been derived from glacier action, and more recently than the paper, which we are reviewing, a notice by him was read before the American Philosophical Society showing that the Monongahela flowed directly northward by the upper Ohio, Beaver, Mahoning and Grand Rivers of Ohio (the last three reversed in Preglacial times) to Lake Erie, thus adding another important tributary to the Erie Basin and further changing the physical features of the Continent.

This paper, which is the first preliminary notice of his work on the Great River Age, will do much to draw attention to the interesting subject which is destined to have an equal place with Glacial Geology, with the extreme views of which it will be found to conflict more or less.

ON M. C. FAURE'S SECONDARY BATTERY.

The researches of M. Gaston Planté on the polarization of voltameters led to his invention of the secondary cell, composed of two strips of lead immersed in acidulated water. These cells accumulate and, so to speak, store up the electricity passed into them from some outside generator. When the two electrodes are connected with any source of electricity the surfaces of the two strips of lead undergo certain modifications. Thus, the positive pole retains oxygen and becomes covered with a thin coating of peroxide of lead, while the negative pole becomes reduced to a clean metallic state.

Now, if the secondary cell is separated from the primary one, we have a veritable voltaic battery, for the symmetry of the poles is upset, and one is ready to give up oxygen and the other eager to receive it. When the poles are connected, an intense electric current is obtained, but it is of short duration. Such a cell, having half a square metre of surface, can store up enough electricity to keep a platinum wire 1 millim. in diameter and 8 centims. long, red-hot for ten minutes. M. Planté has succeeded in increasing the duration of the current by alternately charging and discharging the cell, so as alternately to form layers of reduced metal and peroxide of lead on the surface of the strip. It was seen that this cell would afford an excellent means for the conveyance of electricity from place to place, the great drawback, however, being that the storing capacity was not sufficient as compared with the weight and size of the cell. This difficulty has now been overcome by M. Faure: the cell as he has improved it is made in the following manner:

The two strips of lead are separately covered with minium or some other insoluble oxide of lead, then covered with an envelope of felt, firmly attached by rivets of lead. These two electrodes are then placed near each other in water acidulated with sulphuric acid, as in the Planté cell. The cell is then attached to a battery so as to allow a current of electricity to pass through it, and the minium is thereby reduced to metallic spongy lead on the negative pole, and oxidised to peroxide of lead on the positive pole; when the cell is discharged the reduced lead becomes oxidised, and the peroxide of lead is reduced until the cell becomes inert.

The improvement consists, as will be seen, in substituting for strips of lead masses of spongy lead; for, in the Planté cell, the action is restricted to the surface, while in Faure's modification the action is almost unlimited. A battery composed of Faure's cells, and weighing 150 lbs., is capable of storing up a quantity of electricity equivalent to one-horse power during one hour, and calculations based on facts on thermal chemistry shows that this weight could be greatly decreased. A battery of 24 cells, each weighing 14 lbs., will keep a strip of platinum ⅝ths of an inch wide, 1-32nd of an inch thick, and 9 feet 10 ins. long, red hot for a long time.

The loss resulting from the charging and discharging of this battery is not great: for example, if a certain quantity of energy is expended in charging the cells, 80 per cent of that energy can be reproduced by the electricity resulting from the discharge of the cells; moreover, the battery can be carried from one place to another without injury. A battery was lately charged in Paris, then taken to Brussels, where it was used the next day without recharging. The cost is also said to be very low. A quantity of electricity can be produced, stored, and delivered at any distance within 3 miles of the works for 1½d. Therefore these batteries may become useful in producing the electric light in private houses. A 1250 horse-power engine, working dynamo machines giving a continuous current, will in one hour produce 1000 horse-power of effective electricity, that is to say 80 per cent of the initial force. The cost of the machines, establishment, and construction will not be more than £40,000, and the quantity of coal burnt will be 2 lbs. per hour per effective horse-power, which will cost (say) ½d. The apparatus necessary to store up the force of 1000 horses for twenty-four hours will cost £48,000, and will weigh 1500 tons. This price and these weights may become much less after a time. The expense for wages and repairs will be less than ¼d. per hour per horse-power, which would be £24 per day, or £8800 a year; thus the total cost of one-horse-power for an hour stored up at the works is ¾d. Allowing that the carriage will cost as much as the production and storing, we have what is stated above, viz., that the total cost within 3 miles of the works is 1½d. per horse-power per hour. This quantity of electricity will produce a light, according to the amount of division, equivalent to from 5 to 30 gas burners, which is much cheaper than gas.—*Chemical News.*

MICROSCOPY.

We offer the following notes culled from the pages of the *Journal of the Royal Microscopic Society*:—

A singular species of Ncarus is described by A. D. Michael, found by him at Land's End, England. It belongs to the genus *Dermaleichus* (Koch) *Analges* (Nitsch) but does not fit into any of the five genera, or sub-genera, into which Robins has divided the group. The leading feature in this curious creature was that the male had the left leg of the second pair conspicuously larger than its fellow on the right side, had a totally different tarsus, and supported by a different and more powerful epimeral and sternal arrangement. This deformity makes this species entirely different to any other *Ncarus.*

Haustein has observed in the central cells of *chara*, chlorophyll-bodies containing starch which could not be regarded as the product of assimilation. C. Dehnecke has now investigated a number of similar instances, in which the starch contained within the chlorophyll-grains appears not to serve the purpose of immediate assimilation, but to be stored up as a reserve material.

A new stereoscopic eye piece has been arranged by Professor E. Abbe. The special feature of this instrument

is the ingenious arrangement whereby, by simply turning the caps with the diaphragms, orthoscopic or pseudoscopic effect can be produced instantly at pleasure. It is more particularly available for tubes of short length for which the Wenham prism is inapplicable.

Powell and Leland have completed a new 1-12 having two front lenses. The maximum numerical aperture is 1.43 (= 140° in crown glass of mean index 1.525), obtained by a front lens several degrees greater than a hemisphere, mounted on a plate of glass .003 inch in thickness, which is itself mounted in the usual metal work by the zone projecting beyond the circumference of the lens. With this front lens the focal distance from the exposed surface of the plate on which the lens is mounted is .007 inches. A second front, nearly a hemisphere, is mounted in the usual way by a burred edge of metal covering the extreme margin of the lens. This front gives a numerical aperture of 1.28 (= 115° in glass) and the focal distance is then 0.16 inch. The third front provides a numerical aperture of 1.0 (=82° in glass, as nearly as possible), and the working distance is then .024 inch – probably the greatest working distance hitherto obtained with a 1-12 of that aperture.

Dr. Reidel, an assistant to Professor Abbe, has found two new fluids suitable for homogeneous objectives. The first is a solution of Gum Damar dissolved in hot oil of cedar-wood. The oil which is obtained in Germany has a refractive index of 1.51 *only*, but by the Damar this can be raised to 1.54. If *carefully distilled* it becomes sufficiently pale and loses its stickiness. The other medium is a solution of *iodate of zinc* in Price's ordinary glycerine (n = 1.46). This salt is *very* soluble in glycerine, and a refractive index of 1.56 or more can be obtained, and therefore there is no difficulty in making a solution of 1.52 which is the standard index at 18° cent. Professor Abbe has furnished Mr. Zeiss with a new formula for homogeneous $\frac{1}{8}$, this having a numerical aperture of 1.40 and adjusted for the new fluids.

Mr. T. Charters White, R. M. S., calls for some re-agent suitable for mounting insects; carbolic acid renders the chitinous envelope transparent, but has the same effect on the internal organs also. Dr. Mathews also objected to carbolic acid, as it caused the abdomen of insects thus mounted to collapse. Those who have had some experience in making preparations for insect anatomy will perhaps have suggestions to make.

We lately called attention to infusoria found in cases of epidemic catarrh, called *Asthematos ciliaris*. Dr. Leidy doubted the character of this form and suggested its being a *ciliated epithelium*. Dr. Carter now maintains that it is correct to call it an infusorium, because by culture in mucus outside the body, they increase in number, and they are found in morbid secretions of the conjunctiva where no ciliated epithelia exist—moreover, those remedies only cure the disease which kill the *Asthematos*.

THE STEREORACHYS.

A new specimen of this gigantic and marvellous reptile from the permian schists of Igornay (Saône and Loire) has been presented by M. Gaudry, who gives an exceedingly interesting description of it. Among the results formulated by the learned paleontologist, one of the most striking is the continuity of life of the primary epoch to the secondary one. We are tending more and more to the idea of the slow modifications of terrestrial conditions, and are therefore receiving more and more from the gratuitous supposition of the revolutions of the globe.

To the Editor of "SCIENCE:"

DEAR SIR:—In the last number of your valuable periodical, at the close of a review of Professor Packard's work on the "Brain of the Locust," the writer states: "In view of the loudly trumpeted theory recently revived by Dr. J. J. Mason, after having repeatedly received the *coup de grâce* at the hands of Stieda, Meynert and others that large cells are motor, it is interesting to note that those of the optic ganglion in the locust are among the largest cells in its nervous system."

This is a complete error, so far as I am concerned. No such claim has ever been made by me in any form, by hint, inference or otherwise. In my last paper on the dimensions of nuclei there appears this sentence: "At the same time it may be true that all large cells connect with motor filaments. The sentence which immediately precedes this one clearly proves that I refer here exclusively to the spinal cord of turtles. This is reviving no theory.

Yours truly,

JOHN J. MASON.

NEWPORT, *June* 13, 1881.

SUN SPOTS.

The following record of observations, made by Mr. D. P. Todd, Assistant, has been forwarded by Prof. S. Newcomb, U. S. Navy, Superintendent Nautical Almanac Office, Washington, D. C., to Gen. H. B. Hazen.

DATE. APRIL, 1881.	NUMBER OF NEW		DISAPPEARED BY SOLAR ROTATION.		REAPPEARED BY SOLAR ROTATION.		TOTAL NUMBER VISIBLE.		REMARKS.

SCIENCE:

A WEEKLY RECORD OF SCIENTIFIC PROGRESS.

JOHN MICHELS, Editor.

PUBLISHED AT

TRIBUNE BUILDING, NEW YORK.

P. O. Box 3838.

SATURDAY, JUNE 25, 1881.

NOTICE TO CORRESPONDENTS.

The writer of a paper "*On Ether*" will much oblige by forwarding his name and address.

THE DISCOVERY OF NEPTUNE.

The brilliant theoretical discovery of this planet by Leverrier and Adams, will be distinctly remembered by many of our readers. Soon after the publication of the mathematical investigation made by the two astronomers who had won so much glory, Professor Benjamin Pierce, of Harvard College, startled the scientific world by the announcement that after all this discovery was only a happy accident, and that the planet found by Galli, in accordance with the directions of Leverrier, was not the planet "to which geometrical analysis had directed the telescope." This statement by Professor Pierce has, we believe, found but little credence among European astronomers and mathematicians. Among those who were well qualified to judge, and who may be considered as free from from national prejudice on this question, we mention Hansen, the well-known theoretical astronomer of Germany, and Jacobi, one of the ablest mathematicians of the same country; both of whom expressed the opinion that Professor Pierce was himself mistaken. In a posthumous book recently published on "Ideality in the Physical Sciences," edited by his son, Professor J. M. Pierce, the present professor of mathematics in Harvard University, Professor Pierce reiterates his former opinion on the discovery of Neptune. It appears that a few years before his death he had made a careful review of his former investigations, and says, p. 173: "I strictly adhere to the correctness of my early statement." This opinion seems to be shared also by Professor J. M. Pierce, who says, p. 201 of the Appendix: "It is to be regretted that the correction of the error was not received, on the part of the French astronomer, with the magnanimity and fairness which it is always painful not to find associated with high intellectual power."

Intrinsically, the question raised by Professor Pierce is an interesting one, and the whole matter seems to us worthy of a new and careful discussion. It may well be doubted whether the argument used by Professor Pierce, that there is a change in the character of the perturbations near the distance of 35.3, will apply to the method employed by Leverrier and Adams in their discussion of the perturbations of Uranus. This method is so interesting that we invite the attention of students of theoretical astronomy to this question, which seems to us capable of a complete and definitive mathematical solution.

VIVISECTION.

Dr. Darwin in a letter to a friend has expressed his views upon vivisection. He writes:

"I know that Physiology cannot possibly progress except by means of experiments on living animals, and I feel the deepest conviction that he who retards the progress of Physiology commits a crime against mankind. Anyone who remembers, as I can, the state of this science half a century ago must admit that it has made immense progress, and is now progressing at an ever-increasing rate. What improvements in medical practice may be directly attributed to physiological research is a question which can be properly discussed only by those physiologists and medical practitioners who have studied the history of these subjects; but so far as I can learn, the benefits are already very great. No one, unless he is grossly ignorant of what Science has done for mankind, can entertain any doubt of the incalculable benefits which will be derived from Physiology, not only by man, but by the lower animals."

PROBABLE BRANCHIAL ORIGIN OF THE THYROID AND THYMUS GLANDS.

By S. V. CLEVENGER, M.D.

There are many reasons for believing that the thyroid and thymus are rudimentary gills, one of the main objections to the view being the structure of these bodies, but in the light of modern biology, structure is almost meaningless in homologizing, besides, the tissues of these parts are not the same in all animals. Owen (Vol. I. p. 565) says the thymus appears in Vertebrates with the establishment of lungs as the main or exclusive respiratory organ. In Siren and Proteus the thymus is wanting, as in all fishes. Gegenbaur (p. 554) speaks of the thyroid as an organ with unknown physiological relations, and that "in fishes it is placed not far from the point at which it was formed, that is, at the anterior end of the trunk of the branchial anterior and between it and the copula of the hyoid arch. In amphibia near the larynx, and is set on the inner surface of the posterior comna of the hyoid." Gegenbaur considers it as an organ of use among Tunicata. This latter idea, as well as the one I have advanced, needs verification. I am unwilling to devote more time to the subject until I can ascertain whether some one has not preceded me in announcing the homology, if it be really one. Much light can be thrown upon the disease known as Goître by clearing up this point.

THE ADDRESS OF THE PRESIDENT OF THE ROYAL MICROSCOPICAL SOCIETY.

LIONEL S. BEALE, F. R. S.

As it is usual on this occasion for the President to deliver an address, I venture to offer for your consideration this evening some suggestions in connection with a subject which in one or other of its aspects must needs be of great interest to every one who wishes to learn all he can about the wonderful changes which continually go on in all living things, some being within and some beyond the present limit of scientific investigation; and though I shall express some views with which perhaps many here will not agree, I trust my remarks may kindle interest and encourage discussion, rather than offend. Where wrong I shall be glad to be corrected, but I claim permission to speak freely what I think, and liberty to advance my conclusions, which, though not at present very popular, may yet be worthy of your consideration.

THE MICROSCOPIC LIMIT, AND BEYOND.

Increased skill and ever-extending knowledge may enable the scientific worker not only to reach the utmost limit of inquiry in his time, but possibly to gratify that constant desire to see into the limitless region which lies beyond the bounds of actual investigation. This is the hope which encourages the thoughtful observer; for who would not consent to spend years in patient research, if by so doing he could succeed, as it were, in projecting his intellect, were it ever so short a distance, beyond the circumscribed region in which the senses can alone operate? Failures and disappointments may be endured if only the observer's mind be buoyed up by the hope that ere his nerve-tissues grow too old, and begin to fail, the longing of his intellect will probably be gratified. To many, indeed, who are unable or unwilling to look into the secrets of nature, such hopes and desires will seem unintelligible or incredible. They will be regarded as the idle fancies of an idle mind; and the ardent scientific inquirer will be pitied or condemned as a weak, foolish person who, like a child, is unable to repress his morbid curiosity to peer into the unseen, and his craving to know the unknowable;—as one deserving to be classed with simpletons and madmen, on the ground that it is absurd to suppose that a really sensible person would spend his life in hard work without remuneration, in preference to doing that which would enable him to gain wealth, and to live at ease, if not in luxury and enjoyment. And certainly it must be confessed that in few departments of research is there less prospect of gaining by success such rewards as are generally sought for, than in the one to which we are attached.

The microscopist, like the astronomer, is ever longing to get a little beyond the point at which he has already arrived. Each new fact gained by research seems but to indicate the existence of more and more important things beyond. Limit is reached and then surmounted, but soon a new limit seems to rise from the mists in the distance, towards which the worker is impelled by new hopes and desires. It is this never halting progress which distinguishes scientific from every other kind of inquiry, and particularly microscopical investigation, for it can never be completed. It deals with the illimitable. The boundaries of to-day are found to have vanished tomorrow, and the eyes and understanding begin to penetrate into regions which but a short time before had been considered far beyond the range of possible investigation.

He only who was quite ignorant of the many and great improvements constantly being made in our methods of research, and in the instruments required in investigation, would think of fixing any limit to the advance of microscopical inquiry. The records of the work of this Society contain many examples of progress towards and advance beyond barriers regarded not very long before, and by considerable authorities, as insurmountable. I well remember the time when in many branches of inquiry, it might have been truly said that the optical instrument was in advance of the methods of examination; when our magnifying powers were higher than we could use without losing rather than gaining as regards the definition of delicate structure. As, however, time went on, this was changed. New and improved methods of examining tissues were discovered, and means adopted, by which excessively thin layers could be submitted to examination, and a power of five or six hundred diametres was no longer sufficient to enable the observer to see all that it was almost certain was to be seen. These remarks more particulary apply to a class of researches upon which I was engaged in 1856-60, concerning the structure and arrangement of the ultimate nerve-fibres in various tissues and organs. Indeed, I feel quite sure that at and before that time advance was actually retarded by the discouragement offered in some quarters, and the hypothetical objections raised to the use of very high powers, and more especially to the methods of preparation of the tissues that were necessary before they could with any advantage be submitted to examination.

Although at this time we can work easily with a twelfth and a twenty-fifth, the results of observation conducted with the aid of such powers are still regarded by some with doubt and incredulity; and if we draw attention to actual structure and arrangement discovered by the higher powers, which could not possibly be demonstrated with the aid of a more moderate lens, our statements may possibly be met with insinuations that what was advanced as the result of observation was, after all, discovered by the imagination only.

Our present limit of observation in investigations on the structure and action of the tissues of man and the higher animals, in my opinion, includes the use of magnifying powers of upwards of 2000 diameters. Objects considerably less than the hundred-thousandth of an inch in diameter can be studied with success, but how much less than these dimensions cannot, I think, be determined with accuracy at this time; for so much depends upon the character of the object, and a number of small points of detail as regards the mode of examination. All who are accustomed to work with high magnifying powers are well aware of the great advantages gained by some very slight change in the degree of illuminating power, the direction and concentration of the rays of light, and very slight and happy alterations in the focus, which may momentarily reveal to the mind new facts of the greatest importance after, perhaps, many hours of careful but almost profitless study.

But in other departments of microscopical research, our present means of investigation enable those familiar with the requisite methods of inquiry to demonstrate characteristics of structure far more intricate and minute than the remarks just made would lead you to infer. Various modifications in immersion lenses and in immersion media have greatly contributed to advance our knowledge of structure and action in the lower forms of life; and there is every reason to think that, as time goes on, methods of observation will be still improved and new methods discovered, and that in consequence conclusions already arrived at will have to be greatly modified or entirely changed. Not only so, but by the aid of photography things dimly seen by the eye may be very distinctly and correctly delineated, and with a perfection of accurate detail which a few years ago we should not have supposed to be possible. In all probability, the application of photography to investigations opon minute structural details will be carried far beyond anything yet reached, although it is really wonderful how much has been achieved up to this time

As regards direct observation, with the aid of very high magnifying powers, upon animal tissues, a department of

microscopical work which has engaged much of my attention during many years, I would remark that many observations have been made upon the structure and arrangement of the most delicate nerve-fibres less than the hundred-thousandth of an inch in diameter, and other tissue-elements of very small insects. With due care, facts are ascertained which could not have been demonstrated with the aid of object-glasses magnifying less than from 2500 to 3000 diameters. Not only is the demonstration of structure and arrangement satisfactory, but in many cases a conception of the action and working of the textures during life has been formed, which would not otherwise have been obtained. The exact relation of certain delicate nerve-fibres to the living matter of the nerve in special organs has been determined, and many elementary facts necessary for the determination of the changes constituting nerve action have been ascertained.

To my mind, however, the study, with the aid of high powers and various improved means of examination, of the phenomena which occur in living matter during life, transcends in importance at this time all other inquiries in which the Microscope takes a leading part. For these changes characterize every form of living matter at every period of its being, and in every condition of health and disease. In every form of living matter which exists or has ever existed, the great mystery of life and death is enacted under our very eyes, but we have not yet been able to discover the exact nature of the change, though we can prove most conclusively that it is not merely mechanical or chemical, as some pertinaciously insist. No chemist or physicist has been able to explain the changes which do occur, or has succeeded in imitating them out of the living body. The most diverse structures and the most widely different chemical compounds are produced by changes occurring in particles of living matter which could not be distinguished from one another, and which are equally devoid of color and structure. Many of the current theories on the nature of vital phenomena are in advance of some that were propounded two thousand years ago; and yet men occupying high scientific positions are found to defend them, and to repeat again and again statements concerning the relation between the living and non-living, which are at variance, not only with facts familiar to every one, but are contradicted by the experience and knowledge every person possesses concerning certain vital phenomena of his own organism

When a particle of living matter is increasing in size —is growing by taking lifeless matter into its substance, and without itself losing anything, is communicating to certain of the elements of this non-living matter, or to combinations of these, the marvellous powers it possesses —movements take place, it may be in every part of the original mass. These movements are, however, always most observable, most active, and most extensive at some part of the circumference. Occurring now on one side, now on the opposite, it is very improbable that the movements in question are determined by any changes occurring in, or by force belonging to, any non-living matter in the vicinity of the living mass. These remarkable movements are universal in the world of life. They are more accelerated in some kinds of living matter than in others, but they are present in all, and in most are discernible at some time or other during the course of existence. Parts of the living matter continually tend to move away and separate from the rest, not in consequence of any attraction between these and surrounding matters outside, nor from any repelling influence exerted by parts of the mass itself upon other parts. There seems to be an active tendency on the part of different portions of a living mass to move away from the rest and so to detach themselves, and, having acquired vital power, to become independent, and to increase and then divide. This remarkable tendency on the part of every kind of living matter to divide and subdivide begins to operate as soon as the original mass has attained a certain size, and it seems to increase in intensity as the living matter approaches its proper dimensions. Invariably when a certain size has been reached, which, however, is different for different kinds of living matter, division occurs. The size is always, within certain very moderate limits, fixed and definite for the living matter of each particular species of living being. Among the lowest forms of existence, however, no definite limit of size has to be attained before division can occur. Particles smaller than the smallest particles that can be seen with the aid of the highest magnifying powers freely divide and subdivide, and there is reason to think that under certain conditions the division and infinite multiplication of the animate particles may continue for a considerable time, none of them attaining their fully developed form or dimensions. In higher forms of life, premature division of a living mass before it has grown for a proper time and reached a certain size, is very detrimental, and in many cases disastrous; for it is associated with degradation or even complete loss of formative, constructive, and developmental power. In some cases, by the rapid multiplication and division of the particles, the well being of the whole organism is jeopardized, and death may be occasioned by the changes brought about by great increase and rapid growth and multiplication of certain particles of living matter belonging to the blood or to some of the tissues.

When a portion of a mass of living matter moves away from the rest, the moving portion invariably presents a convex surface, of which the portion in the exact centre is of course in advance of the rest and is the point towards which the movement of adjacent portions tends. It almost seems as if one minute portion had moved away from the rest and had dragged with it neighboring portions, the power of the particles constituting which was not strong enough to act in opposition to it or to resist its influence. These seem to yield and follow the one or few particles in which the movement is strongest, and which seem to act the part of leader. It may be that certain particles here and there, having attained a larger size, or from being more active than the rest, move forward and determine the direction which is to be taken by those near. As far as can be seen, multitudes of living particles stream in one direction, the greater number being either carried along by the very few or irresistibly drawn onwards by them. The direction taken by flocks of birds and clouds of insects in still air or upon the surface of smooth ground, and shoals of fishes in water, is evidently determined and often very quickly changed in obedience to impulses affecting a very few of the great multitude of individuals of which the whole body is composed. These movements cannot, however, correctly be compared with those of a mass of living matter, inasmuch as there is no reason whatever for supposing that, in the latter, one particle has the power of choosing and determining, much less of conveying to its neighbors the results of its decision or choice and the request to follow.

It will, of course, be said by some that the remarkable phenomena we are considering are comparable with the movements occurring among iron filings under the influence of the magnet, or with the Brush discharge of electricity, the movements of the streams of highly attenuated moving matter in vacuum tubes, and other changes in place affecting particles of non-living matter. Surely it must be obvious to any one who thinks over the facts of the case that no true analogy has been shown to exist between the movements of living particles and those of any form of non-living matter. Nevertheless, the existence of such analogy is still maintained by a few, although the fallacy of the arguments upon which it is supposed to rest has been many times pointed out.

I dare say that for some time to come it will be most difficult to get a hearing for any views not in accord with the

materialist tendencies of what is miscalled the *science* of our time. Thought is to be crushed, and any speculations are to be condemned which do not happen to favor the arbitrary dogmas of the purely physical school. But no doubt these attempts, like preceding ones of the same order made at different periods of history—although they may succeed for a time, and by them people may be driven away from the truth—will ere long be given up. They may be safely left to the gradual process of disintegration and ultimate dissipation by which these and such-like fancies of physical ingenuity will be disposed of.

As I have shown elsewhere, whenever tissue and other matters peculiar to living beings are to be formed, living matter undergoes change. In fact, the act of forming these things corresponds with the cessation of life in the particles.

Let us now consider the probable nature of the marvellous forces or powers which operate upon the material of the living matter, and determine the relations to one another of the elements or collections of elements of which it consists. By the relations established between the elements shortly before living matter dies, will depend the properties and composition of the resulting formed substances. The changes in each particular kind of living matter are somewhat different, but peculiar to and characteristic of that particular kind, and as regards it, constant and uniform. But no differences in the chemical composition or in any physical characters to be shown in different kinds of living matter, will in any way account for or explain the differences so remarkable in the formed material which is produced by or results from the death of the living matter. Nor do any properties of the particles yet discovered enable us to suggest a plausible physical hypothesis to account for the facts.
